**Biological Control
by Natural Enemies**
PAUL DEBACH

In this concise and fascinating account, Paul DeBach traces the historical background of biological control and examines in detail some of the most famous examples of the discovery abroad of new natural enemies and their importation into the United States and elsewhere to achieve successful biological control. The book outlines the workings and potentialities of biological control and the importance of maintaining an ecological balance is stressed. 'This is a timely and valuable book, written in characteristic style by one of the world's leading biological workers.'

Hard covers £5 50 net
Paperback £2 25 net

**Cowan and Steel's Manual for the
Identification of Medical Bacteria**
Second Edition

Revised by S T COWAN

The second edition of this important and successful practical manual is written primarily for the use of bacteriologists in hospitals and public health laboratories, but is useful to many who work with bacteria.

The manual provides the essential instructions for the identification of medical bacteria. Recent advances in the techniques for the identification of bacteria, such as the use of punched card systems and enhancements, as well as established techniques, are included and also detailed information on all aspects of the subject, resulting in a set of methods for bacteriology.

Some reviews of the First Edition

'The Manual is clear and well produced, written with an authority and insight which is at times almost embarrassing.'

Nature

'It is likely to become an essential part of the equipment of any laboratory in which clinical bacteriology is practised.'

Canadian Journal of Public Health

SOCIETY FOR EXPERIMENTAL BIOLOGY SYMPOSIUM
NO 28

Transport at the Cellular Level

M A SLEIGH and D. H JENNINGS

This volume is concerned with the ways in which living organisms transport materials within, into and out of cells.

A wide range of organisms are dealt with: bacteria, protozoa, algae, fungi, higher plants and animals including mammals and man. This volume brings together information on transport mechanisms in this wide range of organisms so that similarities and differences are compared and contrasted in an effort to understand the nature of the mechanisms involved.

Teachers, research workers and graduate and undergraduate students in cell biology, biochemistry, physiology and pharmacology will find much of interest in this volume.

LONDON MATHEMATICAL SOCIETY LECTURE NOTE
SERIES NO 15

**Analytic Theory of Abelian
Varieties**

H P F SWINNERTON-DYER

The notes are based on a lecture course given by Professor Swinnerton-Dyer in Cambridge in 1973, which gives an introduction to the standard theory of abelian manifolds, and presuppose very little more than a basic course in complex variables. They contain all the material on abelian manifolds which is needed for application to geometry and to number theory. Although they do not contain an exposition of either of these applications, some geometrical results are included.

Limp bound £1 80 net

General Integration and Measure

ALAN J WEIR

A sequel to the author's undergraduate textbook *Lebesgue Integration and Measure*.

In this second volume the author goes on to generalised treatment of the Lebesgue integral to give the Daniell integral and the related general theory of measure. The explanations are simple and detailed with particular emphasis on motivation, the abstract theory being presented by analogy and constant reference to the concrete theory of the earlier volume. There are over 250 carefully selected exercises at the ends of sections, to almost all of which solutions are given.

The book will be used for final year honours courses in pure mathematics, and for graduate courses in functional analysis and measure theory.

£5 70 net

**An Introduction to Fluid Mechanics
and Heat Transfer**

Third Edition

J M KAY and R M NEDDERMAN

This book presents the fundamental ideas of fluid flow: viscosity, heat conduction, diffusion, the energy and momentum principles and the method of dimensional analysis. A major change in this new edition, apart from the introduction of SI units, is the inclusion of a completely new set of problems using modern examples and these are backed up by hints on their solution.

This text is primarily for chemical and mechanical engineering students at universities and polytechnics.

Hard covers £6 30 net

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words, at most they have three or four displayed items (figures and tables)

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, $\exp(a)$ is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note

(i) To refer to several references by the same author at once, only one reference number need be given

(ii) Cite first and last pages

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable, thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238, 1973)

Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note

(i) To refer to several references by the same author at once, only one reference number need be given

(ii) Cite first and last pages

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable, thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words, at most they have three or four displayed items (figures and tables)

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Systeme International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, $\exp(a)$ is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note

(i) To refer to several references by the same author at once, only one reference number need be given

(ii) Cite first and last pages

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed (Butterworth, 1963-65). COLD SPRING HARBOR LABORATORY

SELECTED PAPERS IN TUMOUR VIROLOGY

EDITED BY

John Tooze, *European Molecular Biology Organization*Joe Sambrook, *Cold Spring Harbor Laboratory*

Here for the first time in one volume are the articles, both classic and contemporary, which rank among the most important contributions to our present understanding of tumour viruses.

Designed for use in conjunction with *The Molecular Biology of Tumour Viruses*, the eleven sections into which this book is divided (each prefaced by a brief introduction) contain the most important references cited in the corresponding text chapter.

Truly a comprehensive source for collateral reading on the undergraduate or graduate level, and a book to be read and reread by students and researchers alike.

1974, 1040 pp., illus., index \$14.95, paperback ISBN. 0-87969-112-3

CONTENTS

Origins of Tumour Virology

papers by: Rous, Shope, Noyes, Murray, Little, Bittner, Gross, Harvey, Stewart, Vogt, Temin, Niven, Trentin

Structure and Composition of Polyoma Virus and Simian Virus 40

papers by: Estes, Vinograd, Lavi, Tai, Danna, Morrow

The Lytic Cycle of Polyoma Virus and SV40

papers by: Benjamin, Hoggan, Sambrook, Khoury, Aloni, Ritzl, Sebring, Hartwell

Transformation by Polyoma Virus and SV40

papers by: Macpherson, Todaro, Stoker, Basilico, Aub, Burger, Nicolson, Habel, Black, Gelb, Sambrook, Watkins, Boyd, Khoury, Ozanne

Genetics of Polyoma Virus and SV40

papers by: Fried, Tegtmeier, Dulbecco, Eckhart, Benjamin

The Adenoviruses

papers by: Valentine, Norrby, Wolfson, Pettersson, Lucas, Wall, Baum, Lewis, Williams

Herpesviruses

papers by: Biggs, Melendez, Epstein, Cook, zur Hausen, Hampar, Duff

RNA Tumour Viruses: Morphology, Composition and Classification

papers by: Robinson, Canaan, Duesberg, Nowinski, Hartley, Vogt, Ishizaki, Hanafusa, Weiss, Scheele, Aaronson, Bassin, Rowe, Hartley, Hardy

Replication of Nondefective RNA Tumour Viruses

papers by: Temin, Baltimore, Verma, Duesberg, Molling, Hanafusa, Hill, Humphries

Genetic Transmission of RNA Tumour Viruses

papers by: Huebner, Gross, Lowy, Pincus, Todaro, Weiss, Hanafusa, Pan, Klement, Livingston, Payne, Bentvelzen, Varmus

Genetics of RNA Tumour Viruses

papers by: Martin, Wyke, Vogt, Stephenson

THE MOLECULAR BIOLOGY OF TUMOUR VIRUSES

EDITED BY

John Tooze, *Imperial Cancer Research Fund*

Written by a consortium of highly respected leaders in specific areas of research, this book gathers together for the first time the experiments and hypotheses that have brought the study of tumour viruses to its current dominating position.

Three introductory chapters focus on the history of tumour virus research, the growth of cells in culture, and surface features of cell membranes. These are followed by six chapters on the various DNA tumour viruses and four on RNA tumour viruses.

A basic text for the graduate level, it also contains extensive reference lists for collateral reading.

"... John Tooze and his contributors are to be congratulated for so thoroughly filling an obvious gap in the biological literature."

B.W.J. Mahy, *Cell*

1973, 743 pp., illus., index \$18, clothbound

ISBN: 0-87969-108-5

COLD SPRING HARBOR SYMPOSIA ON QUANTITATIVE BIOLOGY VOLUME XXXIX

Tumor Viruses

Published in two books for easier handling, this volume presents a broad overview of the current status of tumor virus research. Part 1 presents 76 papers dealing with SV40, polyoma and adenoviruses. Subtopics include genome structure and genetics, RNA transcription, replication, transformed cells, and proteins and their synthesis.

The 59 papers contained in Part 2 focus on the herpesviruses, Herpes simplex and Epstein-Barr, and the RNA tumor viruses, including organization of virion RNA genome and genetics, reverse transcriptase, proviral DNA and its transcription, expression of endogenous viruses, and transformed tumor cell surfaces.

Each part consists of approximately 650 pp., is fully illustrated and contains the full two-part index.

Available April, 1975 2-part set \$60, clothbound

New section

As an experiment we plan to introduce a short section at the back of the journal devoted to miscellaneous announcements and requests. Its exact nature will depend on the response, but we expect it to include requests for and offers of accommodation by people going on sabbatical leave or on holiday, personal announcements, and scientific queries addressed to *Nature* readers. Names and addresses will be printed in all cases.

The Illusion of Attitude Change

Toward a Response Contagion Theory of Persuasion

J. M. Nuttin, Jr.

February 1975, approx. 220 pp, £6 40/\$17 00

0 12 522940 2

This monograph focuses on a progressive and systematic theoretical analysis of some dramatic shifts in the attitudes of university students towards a very popular university reform issue. The author believes that the results of this analysis show the classical social attitude concept to be misleading for both the fundamental and applied study of social behaviour.

Contents: The Cohen-Rosenberg controversy and our 1964 research. An experimental challenge of the interpretation of a cognitive dissonance effect. Evidence for an a-cognitive 'dissonant' view. The illusion of past-advocacy attitude change. An evaluative response contagion view of persuasion. Conclusion. Appendix. References. Author index. Subject index.

Published jointly with Leuven University Press

The Biology of Agricultural Systems

C. R. W. Spedding

February 1975, x+262 pp, £7 40/\$19 50

0 12 656550 3

Agricultural systems involve many disciplines and can be considered from several different viewpoints. This book is primarily concerned with the underlying biology of these systems and with the role of animals and plants within them. It does, however, argue that it is not enough to look at the biological processes and components of agriculture in isolation and that they should be understood to be an integral part of the system.

The work discusses the methods available for identifying the relevant biological sub-systems of agriculture as a basis for research, and examines the role of research in developing agricultural biology.

Phytochemical Society Symposia Series Number 11

Proceedings of the Phytochemical Society Symposium, Ghent, Belgium, 1973

The Chemistry and Biochemistry of Plant Proteins

edited by J. B. Harborne and C. F. Van Sumere

February 1975, xiv+326 pp, £11 60/\$30 75

0 12 324668 7

Over recent years there has been little literature devoted specifically to the protein of higher plants, although much has been written about proteins in general, and it is this gap which the present volume is intended to fill.

Contents: Amino acid sequence analysis of plants. Immunochemical investigations of plant proteins. Properties of the physiological changes in storage proteins. The proteins of barley. Mechanism of protein synthesis in higher plants. The biogenesis of plant mitochondria. The biogenesis of chloroplasts. Plant proteins and phenolics. Protein sweeteners. Proteins and taxonomy. Author index. Subject index.

Plants Consumed by Man

B. Brouk

February 1975, approx. 450 pp, £14 80/\$39 25

0 12 136450 X

The aim of this book is to provide a comprehensive survey of plants for human consumption, including all primary food plants, those which yield non-nutritive ingredients such as flavours, colours, thickening agents and the bacteria and fungi which produce edible materials or which are themselves consumed. Also included, is a special section on plants used for smoking and chewing.

Contents: Introduction. Cereals and Pseudo-cereals. Vegetables. Fruits. Nuts. Plant extracts. Flavouring plants. Beverage plants. Fumitories and masticatories. Fermentative micro-organisms. Morphological survey of plants consumed by man. Glossary (An explanation of morphological terms used in the present book). Selected literature. Index.

Breeding Endangered Species in Captivity

edited by R. D. Martin

February 1975, approx. 450 pp., £12 80/\$33 75

0 12 474850 3

This book is the result of the first international conference on the planned breeding of endangered species in captivity, held in Jersey in May 1972. The papers in this collection have been extensively re-edited and re-written in the interim period. The meeting was sponsored by the Fauna Preservation Society and the Jersey Wildlife Preservation Trust.

This extensively illustrated work is the first to deal specifically with the captive breeding of endangered species. With contributions from Sir Peter Scott, Gerald Durrell, Philip Wayre and many distinguished colleagues, it will be of great value to anyone interested in conservation, and it will provide basic reading for zoo curators, academic staff and professional conservationists.

For a descriptive leaflet on any of the above titles, please write to the publishers

Academic Press

London New York San Francisco

A Subsidiary of Harcourt Brace Jovanovich, Publishers

24-28 Oval Road
London NW1, England111 Fifth Avenue, New York
NY 10003 USA

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words, at most they have three or four displayed items (figures and tables)

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Systeme International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, $\exp(a)$ is preferred to e^a if a is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note

(i) To refer to several references by the same author at once, only one reference number need be given

(ii) Cite first and last pages

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable, thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

*A fuller guide appeared in *Nature* (246, 238, 1973)

Cyclic AMP and Adenyl Cyclase

-we've got the measure of both

The only commercially available cyclic AMP kit for

- Direct assay of plasma cyclic AMP without tedious extraction methods or recovery corrections
- Simple and accurate assay of adenyl cyclase activity free from non-specific interference
- Confidence in results by eliminating errors in crude tissue extracts
- Convenient double linear plotting of results and freeze dried reagents for maximum stability and storage time

Our cyclic AMP assay kit makes use of the high specificity and affinity for cyclic AMP of a highly purified and stabilized binding protein from bovine muscle. This is combined with an improved charcoal separation step. The result is freedom from interference in the assay of adenyl cyclase by materials likely to be present in crude tissue extracts. Also by measuring cyclic AMP formed from cold ATP most of the difficulties encountered in adenyl cyclase assays using labelled ATP are eliminated. Full information available on request.

SCIENCE COPY 100

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words, at most they have three or four displayed items (figures and tables)

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Systeme International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, $\exp(a)$ is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note

(i) To refer to several references by the same author at once, only one reference number need be given

(ii) Cite first and last pages

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable, thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238, 1973).

Manpower needs are not so easily estimated

IN A DOCUMENT put about by the Manpower Services Commission of the Department of Employment, the claim is made, amongst others, that in the off-shore oil industry 'immediate and continuing shortages of geologists, petroleum engineers, drillers and divers have been established'. The circumstances surrounding the report—*The discovery of off-shore oil and gas: manpower implications*—are such there must be the gravest doubts that it merits the extensive publicity it has so far received.

The commission, about which you will learn nothing at all on any page (or the cover) of the report—not even its address, telephone number or where it fits into ministerial structure, sponsored Mr David Begg of Nuffield College, Oxford to write a report which could be an overview of manpower implications of the discovery and exploitation of off-shore gas and oil. Mr Begg took only a couple of months over the draft and has now left to do postgraduate research in the United States. Subsequently Mr John Fyfe, of the commission's secretariat, 'up-dated, revised and expanded' the draft, but in publishing it (at least I suppose it's published although it has 'confidential' on the front page) the commission made the odd statement that the views were those of the authors and not necessarily those of the commission. It is mystifying to know why a report is being disseminated for 'interest and assistance' if the commission cannot stand behind it.

Mr Begg seems to have consulted and drawn extensively from about ten more specialised studies in his overview; it is unclear, however, how many people in the industry he spoke to. The result, as one critic put it, is an A+ for the college essay prize but no marks for producing a document of any help to policymakers in deciding what, if anything, should be done by government, industry and educational authorities.

The authors draw heavily on figures from the Petroleum Industry Training Board (PITB), also a Department of Employment agency. PITB forecasts for oil-related employment are based on a projected number of mobile drilling rigs which, the authors admit, was demonstrably in error as early as June 1974. These errors may partly spring from the nature of a multinational, ever-changing industry in which are all sorts of service companies which do not report operations and employment figures to the board. To go on to accept PITB projections on employment merely with the comment that they should be

treated as conservative estimates is a poor substitute for the detailed investigative work that is needed.

As it is, the report, echoing the PITB, sees the number of jobs for geologists/geophysicists rising from 440 in 1973 to 520 (misprinted as 570) in 1980; for petroleum from 190 to 330 in the same period, and for divers from 300 in 1974 to 650 in the late 1970s.

Can skilled men be provided in sufficient numbers? The report, supposedly aimed at this question, never really answers it at all. Amongst geologists, for instance, what evidence is there that there is a shortfall on the 200 that the PITB say can be employed at present? Or that there will be a shortfall on the 220 that could be used in 1980? None at all, and the authors never address the problem, instead tut-tutting that university geology courses are unsuited to the demands of petroleum geology. If the authors instead of rushing into print had chosen to talk to some of the major oil companies, they would have found that the companies run extensive training courses and prefer the unpre-doctrinated graduate. They would also have found that the companies are acquiring geology graduates without difficulty in what one executive described as a buyer's market. And yet the report speaks of having 'established' an immediate and continuing shortage of geologists.

A similarly critical analysis could probably be applied in the other professions. There seems to be an all-too-ready desire to call any differential between present and future needs a shortfall without a serious examination of ways in which the oil industry is likely to respond. And since the industry is multinational, professionals that can't be found in Britain will probably be imported.

In the case of deep-sea diving, where skills will undoubtedly be in demand for many years, the authors choose to use the emotive turn of phrase rather than careful study. Perhaps 'inadequate training and a high fatality rate' is a correct summing-up of the scene, but what confidence can one have that this undocumented charge is anything more than much else in the report—hunch and hearsay?

It may well be true that there will be shortages of skills in the North Sea, but it would be dangerous to base any plan of action on the evidence of this report. The ability of the British government to monitor what is happening under its own nose must be brought into the most serious doubt by this document. □

THE newly formed United Kingdom section of the International Solar Energy Society has set itself a formidable task in the first year of its existence. It is preparing on its own initiative an assessment of the potential usefulness of solar energy in Britain, along the lines of reports recently prepared in Australia and the United States.

A working party of some forty experts in the various branches of solar energy use has been set up with the help of a grant of £5,000 from the Wolfson Foundation under its programme to support research into the better use of Britain's natural resources, and the report on solar energy should be published in September 1975.

Although the outlook for solar energy in the gloomy days of a British winter seems on the face of it distinctly bleak, a measure of the interest in its possibilities, even in northern latitudes, is given by the rapid growth of the UK section since its formation early in 1974. It now boasts a membership of more than 450, second only to the North American section.

A definite check to research into the applications of solar energy in Britain was given earlier this year by the Central Policy Review Staff, the Think Tank, which recommended in its report on energy conservation that it would not be useful to increase government support for such research. One of the aims of the Solar Energy Society's report will undoubtedly be to try to persuade the government otherwise. By definition the members of the society believe that solar energy has a future in Britain in the short term, in the long term as a source of inexhaustible energy when fossil fuels are exhausted, and as one alternative to the large scale use of nuclear power. The problem as they see it is to pinpoint the areas of technology and basic research which can be most usefully developed to serve the special needs of a highly industrialised, densely populated country like Britain, with a climate which is far from ideal.

But there are ways in which solar energy could make an increased contribution to Britain's energy needs fairly soon, in providing supplementary water and space heating. The technology is available and there is already a small commercial solar heater industry in Britain. With the costs of gas and electricity all set to rise to 'realistic' levels, which will mean an eventual rise of some 30% in electricity prices, supplementary solar power, plumbed into existing hot water systems and suitably insulated, for water heating could become very attractive if it were relatively cheap and easy to install. One of the problems the report will have to consider in this context, how-

ever, is the feasibility of installing this sort of heater in existing buildings.

With regard to the longer term ideal of designing new houses and institutional buildings to take more account of solar radiation and perhaps incorporate solar heating devices, economics and social acceptability will probably

Solar energy in Britain

Solar collectors for heating

The UK Section of the Solar Energy Society has got off the ground with a bang. Eleanor Lawrence has been talking to some of its members about the report on the potential of solar energy for Britain now in preparation.

be the main barriers, although there are still technical problems to be evaluated and overcome.

Many of the other applications of solar energy to be considered in the report are far more speculative. Solar energy research is nothing if not multidisciplinary, and architects and engineers rub shoulders with plant breeders and photobiologists. Green plants have solved not only the problem of capturing sunlight but also the vexed question of how to store the energy derived from it, a problem which is currently exercising the brains of everybody involved in the utilisation of intermittent and irregular sources of power.

The section of the working party dealing with agricultural and biological systems will consider plants both as a source of materials, including food, and as a source of fuel. Research is already in progress in Britain to breed and select plants which make a better use of the available solar energy through a longer growing season and an extended range of growing conditions. As to fuel, the fossil kinds represent a non-renewable source of solar energy stored by plants. So, the argument goes, why not use

plants as a renewable source of fuel by converting plants and plant wastes to liquid fuels, gas and char by pyrolysis and fermentation. Problems the report will have to consider here are the availability of suitable plants, land and the technology needed for making use of the products. Plants grown for fuel may not necessarily have to compete for valuable land with plants grown for food, and it is here that research on the better use of available crops and the introduction of previously unconsidered types as food and/or fuel will be of prime importance. One of the main difficulties with any increase in the growing and harvesting of plants for whatever purpose will be the increased amounts of fertilisers needed. A major limiting factor is expected to be the availability of phosphate, a non-renewable resource produced by only a few countries. Recycling of phosphate and other non-renewable fertilisers is therefore an essential prerequisite before any such schemes can be put into operation. In the report prepared by the Australian Academy of Sciences, the long term nature of such work and the necessity for an early start on research was emphasised, a plea echoed by Professor David Hall, of the Department of Plant Science at King's College London, Chairman of the Agriculture and Biological Systems Section of the working party. If funds for such research are not made available very soon so that the problems and potentials can be properly identified, any useful contribution will take even longer to materialise than the twenty years envisaged by Professor Hall.

Similar considerations apply to work on the photochemical and photobiological conversion of solar energy. The study of the photosynthetic apparatus with the eventual aim of developing synthetic or semi-synthetic systems for using solar energy to split water to produce hydrogen in large amounts, say, has enormous long term implications but is threatened in the present times of financial stringency.

There is a greater industrial interest in photovoltaic solar cells because experience has been built up as a consequence of the space programme, but present terrestrial applications are limited to a few specialised uses as at present costs are very high. If components suitable for mass production could be developed costs would soon fall to economic levels opening up new possibilities for the generation of electric power.

Even if it eventually transpires that the potential for solar energy is indeed fairly limited in Britain—the Society's committee remains open-minded on this issue—Britain can hardly afford to miss out on the potentially valuable export market in solar technology. □

international news

EIGHT THOUSAND million francs in the French budget for scientific research means a growth of 13% over 1974—barely enough to keep pace with inflation. It has been described as a marking-time budget, and hardly more could have been expected in the present economic climate. Moreover the new government, coming after a long period when no decisions were taken, has not yet put forward a definitive policy on all aspects of science. Bernard Gregory, director of the Centre National de la Recherche Scientifique (CNRS), recently summed it up in an interview in *Le Monde*, "it won't do much harm to future prospects as the money has been distributed with a view to keeping open all options but it is not a situation which can go on for many years".

The *enveloppe recherche*, as the budget is called, is only concerned with interministerial projects (which fall within the province of the Délégation Générale à la Recherche Scientifique et Technique (DGRST)). Military, telecommunication and aeronautics expenditures are the concern of their own ministries (in 1973 they came to 6,230 million francs). In 1967 2.2% of GNP was devoted to all research, now it is 1.7%. The increase in public expenditure between 1969 and 1973 was only 33%, compared with 69% in Italy and

Changes due in French science

from the staff of La Recherche

95% in Germany.

There will be very few new jobs, this is of particular concern to government laboratories for which the budget gives authority to take on permanently people of specific skills. In 1971, 432 research jobs were created, in 1973, 200, for 1975 only 156 are projected. The Minister of Industry and Research M d'Ornano, criticised for this running down of manpower, replied that one should add to this figure 194 technicians and 264 *vacataire* posts (research workers on short term contracts).

A controlled budget means a restriction on non-current expenditure for new projects. The public sector has not suffered too much in this way—construction of new laboratories or purchase of new equipment can be postponed—but private laboratories living on state funds will feel the pinch, many scientists could find themselves out of work. This was already happening in mid-1974 in the social sciences sector.

There are priority areas, mainly in

the fields of production and distribution of energy. After several stagnant years, the atomic energy commission starts to grow again by 26.7% in current francs. Most of this will go to reactor safety, treating of fuel elements and the storage of nuclear waste. The rest of the energy expenditure (up to F178.4 millions from F116.1 millions in 1974) will go mainly on thermonuclear fusion research and to a lesser degree on energy conservation, solar energy (F12 million) and geothermal energy (F5 million). Nobody contests the high priority for energy, even so, some deputies have qualms about the overwhelming and unthinking emphasis on electricity production.

Other priorities are biology and certain parts of the social sciences. Research with socio-economic ends (environment, urbanism, transport, pollution) still grows but less than it did in previous years. After much hesitation the launcher *Ariane* is kept thanks to deft budgetary transfers and since *Ariane* is interlocked with other projects, space is relatively well supported financially.

Fundamental research, however, as practised at CNRS and in the universities stagnates, there will only be a 7% growth in current francs, and this is causing much worry.

IN France, as in most western countries, the role of scientists in determining the major issues of science policy has been declining since the late 1960s. The large research institutions are, it is true, in general directed by scientists, but these people are so deeply involved in management that they act more as scientific administrators than as practising scientists. The 1958 reforms in these institutions led to the creation of two key bodies, the Délégation Générale à la Recherche Scientifique et Technique (DGRST), having an interministerial coordinating role in science policy under the Prime Minister and the Comité Consultatif de la Recherche Scientifique et Technique charged with advising the government on matters of research policy. This latter consists of a dozen members, *les douze sages* nominated by the government for periods of four years. *Les douze sages* was a lively and important body to start with. In particular, it prepared the research budget in liaison with the DGRST, and although its advice was not always followed it had an active

Wise but powerless

from the staff of La Recherche

role in the first years of the Fifth Republic, a time when many research bodies were constituted or reformed.

French science policy changed after 1965 under M Pompidou. The priority that research had possessed early in the Fifth Republic was no longer there, and ministers for research after 1965 had less political clout than their predecessors. The influence of *les douze sages* waned and that of administrators grew accordingly.

At present the committee has practically no influence and now that the government has announced a reform of science policy machinery, and particularly of the coordinating body of the DGRST, the role of the committee has come into question. The Minister for Industry and Research, M d'Ornano, said in a recent debate on the research budget in the National Assembly "maybe it is time to start those who are involved in research policy thinking about a problem which

has so far passed them by but to which they should not be indifferent—that of society's control over technological development. One of the first things we could do is bring non-scientists, elected politicians and consumer representatives into closer touch with the implementation of new technologies and the definition of new programmes". The president of *les douze sages*, M Brams, has received the mandate to think about possible reform of the committee and to make proposals relevant to d'Ornano's plan. The problem is that of non-scientists being involved in science policy decisions and this issue had already been aired in Mitterand's presidential campaign, when the idea had been put forward of a high ranking consultative committee on science policy whose members would include non-scientists.

The big question is, if twelve becomes fifteen or twenty will the scientific community and even the whole nation be better represented and will the committee have more power and authority than at present?

NIH Director edged out

by Colin Norman, Washington

FOR the second time in two years, the Director of the National Institutes of Health (NIH) has been fired, apparently because of disagreements with other key administration officials over how biomedical research should be managed and funded in the United States.

Last month, Dr Robert S. Stone, who had been NIH Director since May 1973, was asked to resign by Dr Charles C. Edwards, the top health official in the Department of Health, Education and Welfare (HEW). The event immediately evoked a chorus of protests from several prominent biomedical scientists who charged in a statement put out by the Federation of American Scientists that the NIH is being subjected to "unwarranted and counterproductive political control".

Although no official reasons have yet been given, Stone's downfall is widely believed to have resulted from his opposition to further cutbacks in the NIH's budget and also from his failure to see eye-to-eye with Edwards on the role that the NIH should play in the total national health care programme. In any case, the troubles between Stone and the top brass at HEW (of which the NIH is officially a part) are symptomatic of the widespread disquiet within the biomedical research community over the administration's policies for the NIH.

The disquiet stems chiefly from the

fact that the autonomy which the NIH has traditionally enjoyed has been considerably eroded in the past few years. Until the late 1960s there was little scrutiny of the NIH's programmes either by congress or the rest of the administration, but in the past couple of years, there has been a move to exert considerable management control over the NIH from Edwards's office in HEW. In addition the budget for biomedical research has levelled off and there has been considerable redistribution of funds from several areas of research into the politically sensitive cancer programme.

But the chief bone of contention came early last year when the administration proposed to scrap the NIH's training and fellowship programmes. Dr Robert Q. Marston, Stone's predecessor as Director of the NIH, was in fact fired when he resisted that proposal. After that, the administration let it be known that it was considering some radical surgery on the NIH's peer review system. Although both those moves have since been thwarted, largely because of loud protestations from biomedical scientists, Stone's forced departure is being viewed as yet another move towards tighter political control over the NIH from bureaucrats in HEW.

In an unrelated move, Dr Edwards himself resigned from the government to take up a post in industry a week after Stone's resignation was made known. Two top health posts are therefore vacant and the biomedical research community is anxiously waiting to see who will fill them.

University of Ghana celebrates jubilee

DURING the week (November 30 to December 7) the University of Ghana, situated in the Accra suburb of Legon, held its silver jubilee celebrations. In true academic style, the university had arranged lectures and exhibitions as well as two graduation ceremonies—one for the normal crop of last year's graduates and one for the presentation of honorary degrees to distinguished luminaries, including Dr Conor Cruise O'Brien, former Vice-Chancellor of the university.

The silver jubilee celebrations at Legon, like the recent silver jubilee celebrations at the Nigerian University of Ibadan, are certainly justified, for both universities have played a vital role in producing the trained manpower needed to run a newly emergent state. Sometimes the training process has not run particularly smoothly. Legon's celebrations were actually to have been held

last March but student demonstrations led to a closure of all three Ghanaian universities and to the cancellation of the original silver jubilee celebrations for Legon. Dr Alex Kwabong, the University of Ghana's skilful Vice-Chancellor has managed to keep the situation quiet this academic year, however, and the university's stock has risen appreciably since March. Kwabong is a masterful negotiator and diplomat whose leadership and individualistic style, based on the groundwork laid by his predecessors, have helped to secure international prestige and financial aid for the campus.

Although all Kwabong's subordinates may not have his flair for administration, there has been significant growth in the university. The University of Ghana Medical School, which simultaneously celebrated its tenth anniversary, recently started dental and postgraduate courses. In addition, various other programmes such as computer science, journalism and population dynamics have all been set up within

the past two years.

The University has, in the past, been fortunate in attracting distinguished academics and promising young graduates to fill its teaching and research posts. This is, in part, a result of the generosity of the British, Canadian and Dutch governments who provide finance and high level manpower through technical assistance schemes. It is difficult to find Ghanaians of the appropriate calibre to man the nation's universities. The pecuniary rewards overseas, especially in the United States, are so enticing that Ghana, in common with all developing countries, suffers from a severe brain drain.

Overall the university academic staff is 75% Ghanaian but this proportion varies greatly from faculty to faculty.

In the scientific disciplines, where 41% of the professors and lecturers are non-Ghanaians, the loss of promising Ghanaians is most acute. Their absence abroad is most unfortunate, since the high quality of Legon's scientific research was documented in a recent study of the faculty of science funded by the Ford Foundation. The Ford Foundation's report also suggested a vigorous infusion of money and equipment to maintain the existing high standards. Unfortunately, in the present bleak economic climate, no benefactor has as yet been found to fulfil the committee's recommendations.

In a shrewd display of foresight, the Ghanaian government launched "Operation Feed Yourself" in 1972 in an effort to achieve self-sufficiency in food production. The faculty of agriculture met this challenge by expanding its research programme to improve the varieties of tropical rice and sugar cane being grown in Ghana. As a peripheral benefit the expanded production on the research farms has helped both the university, which can now economise by feeding its students some home-grown agricultural produce, and the Legon housewife, who can now buy hitherto unobtainable goods such as pasteurised milk, frankfurters and liver sausage.

Contemplating Legon's success in the past twenty-five years leads to great hopes for the next twenty-five. It is no mean achievement to teach well and to carry out good quality research in a developing country subject to an acute shortage of foreign exchange delays in imports, low indigenous salaries, a rate of inflation of 20% and a lack of technical staff, and where the whole economic climate revolves around the vagaries of a single agricultural commodity—cocoa. The ability to surmount these obstacles speaks well for the dons at Legon who, in the words of the university's motto, have achieved "progress with integrity". □

SIR,—A letter from Gerschenfeld and others concerning the problems of Chilean scientists under the military rule (*Nature*, March 29, 1974) has been answered by Eyzaguirre (*Nature*, July 5, 1974). I feel it my duty to present the view of a Chilean scientist, a witness of the entire process who works in Chile and intends to stay.

Since I do not think *Nature* to be the proper place for a political argument I shall only say that I disagree entirely with Eyzaguirre's interpretation of what happened in Chile. But neither can I accept his statements of facts. I do not deny the data—which refer to the Catholic University—the problem being rather that he would have others believe that the case of the Catholic University is representative of the Chilean universities. Without saying so explicitly, Eyzaguirre conveys that impression by mixing data of restricted significance with a very general and in my opinion superficial assessment of the Chilean situation before, during and after the military takeover.

According to Eyzaguirre, in the Catholic University "only 3.25% of faculty members were removed after the coup." The information I have collected for the University of Chile shows that approximately 30% of the faculty members and 11% of the non-academic staff were dismissed after the coup. The significance of this information stands out when one considers that the University of Chile enrolls 50% of the university students compared with 8% enrolled by the Catholic University.

I have been unable to obtain reliable data concerning the State Technical University, where the military intervention was most drastic. As to the University of Concepción (12.3% of the student population) the information I have points to at least 30% of faculty members dismissed. This figure is also a fair estimate for the Austral University (2% of the student population). It has been asserted that the worst hit have been the social sciences, but the private Technical University Santa María (3.3% of the student population) lost about 25% of its faculty members. I do not have dependable information on the Catholic University of Valparaíso (5.2% of the students) and the University of el Norte (4.2% of the students).

To sum up, the universities that enrol 75.6% of the students have lost about 29% of their faculty members since the military intervention, that is approximately 5,000 people, but dismissals still continue. As to the universities on which I have no consistent data (24.4% of the student population) the percentage of faculty members removed is presumably higher, consider-

ing that the State Technical University was entirely reorganised and is the second largest university in Chile.

The percentages of faculty members dismissed up to now are estimates based on various sources and might require some correction if reliable information is eventually disclosed to the public. Nevertheless, I trust that my estimates—especially those for the University of Chile—would stand a fair test and anyhow they clearly prove that the Catholic University is an exceptional case.

As to how many of the 130,000 university students have lost their

Letter from Chile

Dr Luis Izquierdo of the Faculty of Sciences at the University of Chile describes the situation now obtaining in the Chilean universities

places, dependable information is unavailable at this stage. On the one hand it is still uncertain how many might be allowed to register again, on the other hand, more than one year after the military intervention, students are still being expelled.

Eyzaguirre claims that faculty members removed from the Catholic University had been "engaged exclusively in different forms of political activity." Of course, political activity was not forbidden before the military intervention and nobody should be retrospectively condemned unless proven that he or she was exclusively engaged in these activities, since it is not the role of universities to support full time professional politicians either from the right or left. But, have there been thorough investigations?

It might be again the exceptional case of the Catholic University and hence the low percentage of faculty members removed. It is certainly not the case of the University of Chile in which faculty members were summarily investigated on the basis of secret denunciations. Charges were unspecified and all the defendant could do was to ask for certificates of good conduct from his less scrutinised friends. The procedure has been so irregular that in practice all decisions rested in the "fiscals" appointed by the military rector. I have witnessed much injustice, persecution and vindictiveness. I also must admit that some "fiscals" accepted their role in this legal farce so as to bring some help to their colleagues in disgrace.

In the State Technical University, University of Concepción and Austral University there was not even the

pretence of a legal procedure. The resolutions were based on black lists and faculty members or students were given notice through a standard form which specified no charges.

A decree from the government forbade universities and public institutions to employ faculty members dismissed, so those who had been engaged in research and teaching for years—notably in the basic sciences—had no alternative but to emigrate if they cared to persevere in their work. How can Eyzaguirre decide for practising *gauchisme de salon* those who left Chile and those lending them a hand from abroad? Of course there are people who have taken advantage of the international benevolence and claimed persecution when really looking for a better job, but they are exceptions and the overwhelming majority could not remain here because they had lost their jobs or felt threatened or could not endure the repressive environment.

The percentage of faculty members dismissed does not show in all its magnitude how serious the loss is for science in Chile. Many more scientists have left because of difficulties encountered in their work, such as disruption of research groups when senior investigators were dismissed, lack of research funds or of up to date libraries. The Chilean Society of Biology includes in its 414 members almost all the biologists at least partially engaged in research, 28% have left not to return under the present conditions. The situation of the Faculty of Sciences of the University of Chile is even worse. After struggling for 10 years we had succeeded in establishing it on a firm basis. Now, of the 123 faculty members in the department of Mathematics, Physics, Chemistry and Biology, 60 have left the country. Some would probably have been dismissed had they stayed, others lost hope of pursuing their research work at a satisfactory pace. Those of us who have invested so much of our time in the organisation of this Faculty, bitterly resent a set-back that takes us again to that state of dependence on foreign countries which we had sought to overcome.

The military intervention in Chilean universities has been up to now mainly repressive and has not achieved a new order. Recognised age-old vices of our university system persist in spite of the almost absolute power of present military rectors.

I have written this letter for the sake of truth to the best of my knowledge, convinced as I am that innuendoes, slander and lies from many quarters have corrupted Chilean political life in the last decade causing much individual misery and social distress.

Towards an anti-viral vaccine for a human cancer

from M A Epstein

WHEN the US National Cancer Institute set up the Special Virus-Leukaemia Program in 1964 (later expanded as the Special Virus Cancer Program) with the explicit objectives of (1) determining whether at least one human cancer is caused by an oncogenic virus, and if so of (2) developing an effective vaccine for the control of such a tumour (Rauscher, Carrese and Baker, *Cancer Res*, **26**, 1176, 1966), the project was viewed with considerable scepticism by many leading workers in the cancer and virus fields. Looking back at the impressive progress made in tumour virology over the last ten years, the far-sightedness of the whole project is now evident, particularly in relation to the herpesviruses following striking recent advances with vaccines against some oncogenic members of the group.

Herpesviruses are known to cause the ubiquitous Marek's type of malignant lymphoma in chickens (Churchill and Biggs, *Nature*, **215**, 528, 1967; Solomon *et al.*, *Proc Soc exp Biol Med* **127**, 173, 1968), an experimental malignant lymphoma in South American sub-human primates (Meléndez *et al.*, *Lab Animal Care*, **19**, 378, 1969), and the Lucké kidney carcinoma of the leopard frog (Mizell *et al.*, *Science*, **165**, 1134, 1969; Naegele *et al.*, *Proc natn Acad Sci USA*, **71**, 830, 1974), and the closeness of the association of Epstein-Barr virus with African Burkitt's lymphoma and nasopharyngeal carcinoma in man is increasingly suggestive of some aetiological relationship (Epstein and Achong, *A Rev Microbiol*, **27**, 413, 1973; Klein in *The Herpesviruses*, edit by A Kaplan, Academic Press, London and New York, 1973; Henle and Henle, *Cancer Res*, **33**, 1419, 1973). There is also a more tenuous association between herpes simplex virus type II and carcinoma of the human cervix (reviewed by Rapp and Buss, *Am J Pathol*, **77**, 85, 1974), but this has been weakened by the failure of biochemical probes to detect the viral genome in tumour biopsy cells (zur Hausen *et al.*, *Int J Cancer*, **13**, 657, 1974).

The development in 1969 of live, attenuated herpesvirus vaccines capable of giving chickens almost complete

protection against Marek's lymphomas (Churchill *et al.*, *Nature*, **221**, 744, 1969; Okazaki *et al.*, *Avian Dis*, **14**, 413, 1970) was of great significance both in economic terms and because it provided the first example of a naturally occurring malignant tumour to be controlled in this way. Although the importance of this step forward was widely recognised, its applicability to the ultimate control of those human cancers suspected of having a herpesvirus cause was clearly slight because of the impossibility of administering to man a suspected tumour-inducing virus, however attenuated. Indeed, it is unlikely that even an inactivated virus of this kind would ever be usable as a human vaccine because of the difficulty of proving total inactivation and the possibility that traces of the viral DNA in such a preparation might be capable of bringing about malignant transformation. But further progress with oncogenic animal herpesvirus vaccines is beginning to indicate the ways in which these difficulties could be overcome. Thus, it is now known that chickens can be significantly protected against Marek's lymphomas by vaccines free of virus nucleic acid. Lesnick and Ross (*Br J Cancer*, in the press) have reported some success with a vaccine consisting only of soluble viral antigens extracted from Marek's virus-infected tissue culture cells by treatment with nonionic detergent and other workers have used highly purified plasma membranes from similar virus-infected cells as a vaccine, and reduced the mortality from Marek's lymphomas by 94% when the vaccinated chickens were subsequently challenged with virulent virus (Kaaden and Dietzschold, *J gen Virol*, **25**, 1, 1974).

Now Laufs and Steinke (this issue of *Nature*, page 71) have moved the problem closer to man by showing that sub-human primates can also be successfully protected against a herpesvirus-induced malignant lymphoma. These workers have used a combination of heat and formaldehyde to inactivate herpesvirus saimiri, which is otherwise carcinogenic in South American primates, and have shown by complement-fixation tests that the inactivated vaccine maintains consider-

able specific viral antigenicity after these treatments. Forty-two cotton-top marmosets have been immunised with the vaccine in the present experiments, have remained well after this, and have developed high titres of neutralising and complement-fixing antibodies to the virus. So far 22 immunised animals have been challenged with filtered, virulent herpesvirus saimiri in doses many times greater than those needed to induce fatal lymphomas in control animals and at the time of writing all were alive and well between 121 and 293 days after the challenge, whereas inoculated control animals died of malignant lymphoma within 52 days.

It seems reasonable to anticipate that herpesvirus saimiri vaccines free of viral nucleic acid will be developed before long on similar lines to those already being used to protect against Marek's lymphomas in chickens. The possibility this provides of a model system involving animals phylogenetically related to man has important implications for the planning, production, and testing of vaccines against suspected human tumour viruses. In this connection Epstein-Barr virus is not only a leading candidate because of its special association with Burkitt's lymphoma, but also has certain unique advantages. Thus, as has been pointed out elsewhere (Epstein and Achong, *A Rev Microbiol*, **27**, 413, 1973), since Epstein-Barr virus causes infectious mononucleosis the efficacy of any vaccine developed could be tested by its ability to protect those at risk from this disease, and the existence of areas of high endemicity of Burkitt's lymphoma provide populations where the effect of such a vaccine on tumour incidence could be relatively easily tried out. Finally, since Burkitt's lymphoma occurs most frequently around the age of six, vaccination of infants in the months after birth should allow the efficacy of protection against Burkitt's lymphoma to be judged within five to 10 years. It seems that tumour control by an anti-viral vaccine will be the only way of proving whether or not Epstein-Barr virus is a human tumour virus aetiotogically related to Burkitt's lymphoma either with or without additional cofactors.

Circular polarisation in the Crab nebula

from R D Davies

THE Crab nebula—the remnant of the supernova of AD 1054—is a very remarkable object. It is unique in that it has been detected over the entire electromagnetic spectrum from radio through infrared and the visual to X rays and γ rays. Moreover the pulsar with the shortest known period lies at its centre. This pulsar holds the key to the source of energy in the Crab nebula which had been a mystery before its discovery. The pulsar is a neutron star rotating at 30 Hz. The important property of the pulsar in the context of the energy source of the Crab nebula is that it is slowing down—the rate of loss of rotational energy of the pulsar is equal to the energy radiated by the surrounding nebula.

The next stage is to understand the mechanism by which the pulsar supplies energy to the nebula. This energy is evident in the form of relativistic electrons and magnetic fields as these are required to produce the synchrotron emission from the nebula. But a simple estimate of the lifetime of the relativistic electrons which are responsible for the optical continuum emission indicates that they have a lifetime of only a few years. As a consequence such high energy electrons must be replenished continuously. This point was clearly recognised in the earliest work on the topic. Oort and Walraven in 1956 suggested that the moving wisps of gas seen near the centre of the nebula were evidence of continuing activity from a central star.

Recently Rees and Gunn (*Mon Not R astr Soc*, **167**, 1, 1974) have looked afresh at the problem of the supply of relativistic electrons and magnetic fields to the nebula. They took a theory originally proposed by Piddington in 1957 and discussed subsequently by Kardeshev which had a central object responsible for winding up the magnetic field and thereby maintaining its strength. Rees and Gunn showed that the magnetic flux through the object increases in proportion to the number of rotations of the central pulsar; this indicates that as the nebula ages the magnetic field becomes increasingly important. The configuration of the field will be toroidal with an axis parallel to the spin axis of the pulsar. This axis is taken to lie along the major axis of the nebula (NW–SE). Linear polarisation measurements at optical and radio wavelengths show that the magnetic field is uniform and is essentially perpendicular to the major axis as would be expected from a toroidal configuration if the axis of rotation is in the plane of the sky.

Synchrotron theory indicates that more stringent tests can be made of the field configuration by measuring circular polarisation. Legg and Westfold (*Astrophys J*, **154**, 499, 1968) made a detailed analysis of the polarisation produced in the synchrotron mechanism and showed that a small component of circular polarisation is present. The sense of the circular emission depends on the inclination of the line of sight to the normal to the magnetic field, while the degree of polarisation is proportional to the square root of the magnetic field divided by the frequency. Such circular polarisation has already been detected in the radio emission from the magnetosphere of Jupiter and from several flat spectrum (that is, compact) extragalactic radio sources. It is now of interest to see if circular polarisation can be detected in the Crab nebula in the configuration suggested by the Rees and Gunn toroidal field model. Optical measurements by Martin *et al* (*Mon Not R Astr Soc*, **159**, 191, 1972) showed the presence of a weak circular polarisation but it is believed that this is produced by dust in the interstellar medium lying between the Crab nebula and the Earth.

No similar effect is produced by dust at radio wavelengths. An interesting new measurement of significantly higher sensitivity than made previously is now forthcoming. Weiler (this issue of *Nature*, page 24) reports the detection of circular polarisation in the radio emission from the Crab nebula at 1,415 MHz. Using the Westerbork Aperture Synthesis Radio telescope he finds a fractional polarisation of about 0.05% in four regions in the nebula. The circular polarisation is however of one sense only and does not show the change of sense in adjacent quadrants predicted on the toroidal model. Weiler concludes that the simplest magnetic field structure consistent with his observations is that of a relatively uniform field of 10^{-3} to 10^{-4} gauss with its line of sight component directed towards the Earth. On the face of it Weiler's detection is significantly above his measurement errors, although as he himself admits, independent confirmation would be useful at a lower frequency ($\lesssim 1$ GHz). If indeed this result is confirmed we are left with the need for a mechanism to maintain and amplify the magnetic field of the Crab nebula.

Models of nitrogen fixation

from A J Thomson

THE ability of primitive bacteria and some blue-green algae to reduce atmospheric nitrogen to ammonia at ambient temperature and pressure has long been a provocation to inorganic chemists. Until the mid-1960s, the only other known reaction of nitrogen at room temperature was the formation of metal nitrides either on clean metal surfaces or by lithium and alkaline earth metals. Considerable progress has been made in the isolation and analysis of the enzyme, nitrogenase, responsible for biological fixation (Hardy, Burns and Parshall, *Adv Chem Ser*, **100**, 219, 1971). High purity preparations are now available from three genera of bacteria, including *Azotobacter vinelandii* and *Clostridium pasteurianum*. The enzyme, which requires an electron source such as ferredoxin or sodium dithionite, can be separated into two proteins, a high molecular weight component containing one or, less probably, two atoms of molybdenum and about 15 atoms of iron per molybdenum atom. The smaller protein contains two atoms of iron and two ions of 'labile' sulphide. Little is known about the environment of the metal atoms, although the high sulphur content of the protein

has led to the suggestion that sulphur is a ligand. There is no direct evidence that the metal atoms are directly involved in binding nitrogen during fixation.

The discovery by Allen and Senoff (*Chem Commun*, 221, 1965) of the first metal dinitrogen complex, $[\text{Ru}(\text{NH}_3)_5(\text{N}_2)]^{2+}$, during the attempted synthesis of $[\text{Ru}(\text{NH}_3)_6]^{2+}$ by the reaction of hydrazine with ruthenium trichloride trihydrate in water showed that N_2 could be made to ligand to metals. This was an important step since it had been a puzzling feature of inorganic chemistry that, whereas so many carbon monoxide complexes of low-valent metals were known, the isoelectronic N_2 molecule was apparently unable to bind. Since this observation some fifty complexes of dinitrogen have been reported (Sellman, *Angew Chem Int Edit*, **13**, 639, 1974). It is now a tacit assumption of all model studies that a metal ion, most probably molybdenum, is responsible for binding dinitrogen in nitrogenase.

The primary process of fixation, the trapping of the nitrogen molecule at ambient partial pressure, has now been successfully modelled by several groups using well defined compounds. A group

A hundred years ago

A RARE phenomenon, says the *Malta Times*, occurred in the forenoon of Monday, the 21st ult. During a strong wind from the south-west, which had prevailed for two days previously, the sea suddenly rose several feet and flooded the moles and roads surrounding the harbours, causing four or five steamers, moored between the Custom House and Calcara Rise, to snap their stern hawsers like packthreads, and carrying away boats that were hauled ashore in the French and other creeks. The sea then receded as suddenly as it rose, leaving portions of the bottom of the harbour exposed, upon which men and boys might be seen collecting fish and other marine animals that had been left aground by the retiring water. Shortly afterwards the sea resumed its ordinary level. Similar phenomena have been noticed occasionally during the course of many years.

From *Nature*, 11, 196, January 7, 1875

from the Agricultural Research Council Unit of Nitrogen Fixation at the University of Sussex were first to devise a reaction based, appropriately, on a molybdenum complex (Bell, Chatt and Leigh, *Chem Commun*, 482, 1970)

Subsequently, both Soviet and American teams succeeded in preparing

from gaseous nitrogen under mild conditions (Yu *et al.*, *Chem Commun*, 1178, 1972; Bercaw, Marvich, Bell and Brintzinger, *J Am Chem Soc*, 94, 1219, 1972; van Tamelen, Cretney, Klaentschi and Miller, *Chem Commun*, 481, 1972)

The second step required in the fixation process, the reduction of coordinated nitrogen to ammonia, has proved exceedingly difficult to achieve in any of the characterised complexes. Most attempts at reduction led to displacement of nitrogen. For example, solvolysis of $[(\text{C}_5\text{H}_5)_2\text{Ti}]_2\text{N}_2$ with methanolic HCl yields mainly nitrogen although ammonia and hydrazine appear as minor products. The first step in a well characterised partial reduction was achieved by Chatt, Heath and Richards in a reaction of their molybdenum (or tungsten) bis-dinitrogen complex with concentrated HCl (*Chem Commun*, 1010, 1972)

Now the persistence of the Sussex team has been rewarded. A report appearing in this issue of *Nature* (page 39) shows the room temperature reduction in a methanol/sulphuric acid solution of *cis* or *trans*- $[\text{Mo (or W)} (\text{N}_2)_2(\text{PR}_3)_4]$ to two molecules of ammonia and one of nitrogen. The yields of ammonia go as high as 90% per nitrogen molecule reduced for a *cis* tungsten complex. Recently an interesting parallel development occurred in the United States, with the demonstration of the partial reduction of dinitrogen bound to a zirconium analogue of the cyclopentadienyl complex (Manriquez and Bercaw, *J Am Chem Soc*, 96, 6229, 1974) $[\text{C}_5(\text{CH}_3)_5]_2\text{ZrCl}_2$ undergoes reversible binding of nitrogen slowly at atmospheric pressure in the presence of sodium amalgam to form a binuclear species $[\{\text{C}_5(\text{CH}_3)_5\}_2\text{Zr}(\text{N}_2)]$. At -80°C , this product undergoes reaction with 10 M excess HCl in toluene releasing two molecules of nitrogen gas and forming a white solid, $\text{N}_2\text{H}_4 \cdot 2\text{HCl}$.

There is an interesting contrast between the British and American reactions. The former seems to involve a metal ion oxidation state change of +6 to supply the reducing equivalents to produce two molecules of ammonia from one of nitrogen. In the American scheme, however, a dimeric metal complex supplies only four reducing equivalents to lower the oxidation state of N_2 to N_2H_4 . It has been thought extremely unlikely that the six reducing equivalents could be supplied by a single metal centre. It is a basic tenet of the theory of electron-transfer reactions, borne out by experiment, that probabilities of simultaneous transfers of two or more electrons are very low and indeed, there is now a general doctrine of compulsory one-electron steps in true electron transfer (as opposed to atom transfer) reactions. If reduction is brought about by a cluster of metal ions, a dimer for example, this difficulty is partially overcome. Thus the zirconium complex apparently involves only a two-electron transfer per metal atom. Such electron transfer processes are well known although taking place sequentially. The fact that nitrogenase contains a large number of metal ions lends some credence to the view that a multi-metal centre is responsible for reduction. A somewhat similar hypothesis persists for the terminal oxidases which supply four electrons for the reduction of oxygen to water. The presence of a number of metal redox sites in the enzymes again suggests a cooperative interaction between the centres to supply the necessary reducing equivalents without any one centre undergoing a large change in oxidation state.

For these reasons the claim by the Sussex group to have shown "that molecular nitrogen can be reduced at a single metal centre in a protic medium"

is important. It is clear that, according to the overall stoichiometry of the reaction, each metal ion supplies six reducing equivalents. But since no kinetic or mechanistic evidence is presented in this report, it is surely not yet possible to conclude that reduction has gone on at a single metal centre. The low oxidation states of molybdenum and tungsten are well known for a tendency to form clusters. A recent report (Cotton, Frenz and Webb, *J Am Chem Soc*, 95, 4431, 1973) describes the structures of two dimers of molybdenum, $[\text{Mo}_2(\text{SO}_4)_4]^{3-}$ and $[\text{Mo}_2(\text{SO}_4)_4]^{4-}$. Apparently sulphate ion, the medium used in the Sussex experiments, can bridge two molybdenum ions. Professor Chatt and his colleagues have themselves suggested that the difference between the susceptibility to solvolysis of the diphosphine and monophosphine complexes may reside in the lability towards substitution by sulphate ion of the latter ligand. In addition, they note the escape of one molecule of nitrogen on mixing the reagents. Thus, consideration should be given to the possibility that metal clusters are involved at some stage in multi-step reduction of nitrogen. Some mechanistic studies will clearly be necessary to resolve this problem. Although one may start a reaction with a "well-defined complex" and be able to write down the overall stoichiometry not all the intermediates are thereby defined. Undoubtedly these latest two reactions are going to provide useful models for exploration of the mechanisms and the intermediates by which multi-step reductions can occur.

Future for thin films

from A G Holmes-Stedle

THE table shown on page 9 was composed to stimulate discussion on the limitations and requirements for electronically active thin films when used for making solid-state devices. At present, almost all such devices are dependent on the use of major circuit elements made from single-crystal ingots (for example, most thin-film hybrid circuits contain a silicon transistor chip). The crystal must be grown with immense care, then sliced, polished, diffused and diced. More than 50 processing steps may thus be involved before a minute 'chip' with the required electronic functions is produced. The chip then has to be attached to a header and contacted by thin wires. Techniques are now available to produce many of the same electronic functions in the same volume of material using only thin layers which are deposited on an inert surface and then etched into complex patterns to form minute active circuit elements (see, for example, Maissel, *Handbook of Thin Film Technology*, McGraw-Hill, 1972).

Table 1 Twenty-two electronic devices which could be made entirely of thin films

A Most active material is semiconductor		B Most active material is dielectric
Bipolar transistor	Magnetoresistor	Variable-threshold transistor
MIS transistor*	Photoconductive photosensor	Dielectric filamentary switch
Schottky-barrier transistor	Mechanical transducer	Pyroelectric detector
Rectifier	Chalcogenide switch	Light-beam deflector
Junction photosensor	Chalcogenide memory	Light-beam modulator
MIS electroluminescent diode*	Chalcogenide triode	Storage photosensor
Solar cell	Photostructural switch	
Charge-coupled device	Cold-cathode electron emitter	

*MIS: Metal-insulator-semiconductor

The main technological skill which is still lacking is the ability to deposit films of the required crystal perfection for the performance of certain crucial electronic functions. In conventional single-crystal electronics, effects such as minority-carrier transport, avalanche multiplication, tunnelling, acoustic surface-wave transport are commonly employed to amplify or modify the electrical signal entering the device. If these processes are depressed by the various forms of disorder and defect state found in the thin-film form, then this device principle cannot be embodied in a structure made entirely of thin films. For example, surface acoustic waves (SAW) cannot be transmitted along an evaporated silica film because the film is glassy and hence is not piezoelectric. The SAW signal-processing device therefore does not appear on the table, though it would merit a place if current attempts to make oriented piezoelectric thin films of zinc oxide to serve the same purpose as the conventional quartz chip are successful.

Grown or deposited films may be completely amorphous (see, for example Le Comber and Mort, *Electronic and Structural Properties of Amorphous Semiconductors*; Academic Press, 1973) or may contain very large numbers of grain boundaries, dislocations or point defects. Whether a device should be fabricated by thin-film or single-crystal technology usually depends on the feasibility of controlling the disorder and defect content of the thin film to the required degree and the profitability of doing this on a mass-production scale. That the stakes are high is illustrated by Westinghouse's recent announcement of a flat all-thin-film display panel, measuring about 11 inches diagonally (released at the Institution of Electrical and Electronic Engineers International Electronic Devices Meeting, Washington, 20 October). This device ("The World's Largest Integrated Circuit") is a laboratory product, paid for by the military. Yet a form of it could appear in everyone's living room within a few years, displacing the bulky eye of the television cathode ray tube.

Other concerns are working on similarly attractive, "all-thin-film" possibilities such as the pocket television

camera, the pocket optical computer and the optical waveguide to replace electrical wiring. Some items in the table are well developed commercial devices which are now normally fabricated from ingots; others are still in developmental or conceptual stages. Some further details on the criteria used in making this list may be found in my paper in *Rep. Prog. Phys.* (36, 699; 1974), which deals with the special case of amorphous materials but employs a suitable analytical approach for discussing thin films in general. Note that it is not only semiconductors which must be considered: increasing use is now being made of electronically active dielectrics. Though the single-crystal approach will never be completely displaced, it seems certain that thin-film techniques for electronically active materials have an important future and active discussion between physicists and technologists can only serve to promote the best use of those techniques.

Volcanic tephra on Crete

from Peter J. Smith

EARTH scientists or archaeologists can sometimes obtain information of mutual interest about the past. For example Ninkovich and Heezen (*Colston Res. Soc. Papers*, 17, 413; 1965) concluded from their studies of Mediterranean deep sea cores that tephra from violent volcanic eruptions must have fallen on Crete at least twice in prehistoric times. The older eruption took place more than 25,000 years ago and scattered material throughout the whole island. In the more recent fall, thought to be related to the eruption of Santorini (Thera) about 3,500 years ago, tephra (the so-called Minoan tephra) apparently covered the eastern half of Crete to an average depth of about 10 cm.

At first sight, the new volcanological evidence relating to the more recent eruption seemed to support Marinatos's (*Antiquity*, 13, 425; 1939) earlier hypothesis that the eruption of Thera led directly to the sudden collapse of the Minoan civilisation. But the picture became cloudier when Olausson (*Opera Botanica*, 30, 29; 1971), who also studied deep sea cores, claimed that the

younger tephra identified by Ninkovich and Heezen really comprised three or four layers of different ages, the youngest being not less than 5,000 years old. There is also a problem at the field level in that many archaeologists have found no volcanic ash on Crete at all, and thus remain unconvinced that tephra from the Thera eruption even reached the island.

Moreover, the general archaeological background is not as clear as it might be, for whereas the general destruction on Crete apparently occurred towards the end of the Late Minoan IB stage in about 1450 BC, or 1470 BC at the very earliest, the ruins on Thera itself have so far yielded only one sample of pottery typical of that stage. This strongly implies that there was a gap of several tens of years between the destruction of Thera and that of Crete. But geologists have generally ruled out the idea of two violent paroxysms, pointing out that upheavals which could have produced the pumice observed in the area would hardly have been able to occur within thousands of years of each other. So if there was only one catastrophic eruption, did it destroy Thera (in which case it could not have been the direct cause of the destruction of Crete tens of years later) or did it destroy Crete (in which case archaeologists need to discover why Thera was abandoned tens of years before the eruption)?

A more thorough search for, and study of, Cretan tephra was clearly necessary and has now been made by Vitaliano and Vitaliano (*Am. J. Archaeol.*, 78, 19; 1974). But, first, what are the possible sources of tephra on Crete? There are five Aegean volcanoes with a late Quaternary history of violent explosive eruptions; but three (Nisyros, Yali and Kos) lie to the east-north-east of Crete and are thus considered unlikely sources because the high-altitude dust-transmitting winds in the region are predominantly from the west. This leaves only Melos and Santorini (Thera) to the north. Volcanic material from particularly violent eruptions can however travel very long distances. Some Cretan tephra could therefore come from as far away as Italy; and the 5,000 year old eruption mentioned by Ninkovich and Heezen is now thought to have been Italian.

The question that Vitaliano and Vitaliano set out to answer is thus as follows: can Thera tephra actually be found on Crete, identified as coming from the Minoan eruption of 3,500 years ago, and related to Minoan archaeological levels?

The question became one of the refractive index of glass. On Santorini the tephra overlying the Thera ruins largely comprises volcanic glass with a

refractive index of 1.509. By contrast, the glass from a previous Thera eruption 16,000–17,000 years ago has a refractive index of 1.514, that from Nisyros (though similar chemically to that from Santorini) has an index of 1.502, that from Melos has an index of 1.505 and that from Yali has an index of 1.494. Composition without optical properties is apparently not suitable for the purpose of determining the source of tephra, although a combination of composition and refractive index should be slightly better than index alone.

And tephra with glass of refractive index 1.509 is indeed found on Crete. Vitaliano and Vitaliano have now discovered the Minoan tephra in trace amounts in over 50% of soil samples collected along the eastern section of the north coast. Traces of the tephra are also found at various archaeological sites, though so far never in circumstances thought to represent undisturbed remnants of the original Minoan ash. A few particles of the 25,000-year-old Italian glass (index 1.52) were also found, but none from the 16,000-year-old glass of Thera.

Unfortunately, the quantities, locations and arrangements (with respect to archaeological artefacts) of the Minoan tephra are as yet insufficient to enable firm conclusions to be drawn about the relationship between the eruption and the destruction of Thera and Crete. But having proved the potential of their method, Vitaliano and Vitaliano tentatively conclude that "little or no time elapsed between the abandonment of Thera and the fall of tephra on eastern Crete". Thus the preliminary volcanological evidence suggests that the general destruction of Crete was not a direct result of the Santorini eruption.

The mating game

from our *Animal Ecology Correspondent*

THERE is no doubt that male and female animals play the mating game according to somewhat different rules. Males are usually much more showily dressed than females and are given to attention-seeking displays. Often these take place when there are no females in sight and so cannot be regarded as being for the benefit of the opposite sex. Darwin in 1871 (*Descent of Man and Selection in Relation to Sex*; Murray, London) stated that males competed among themselves for mates while females did not compete but exercised some choice in mate selection. In a thesis which received wide publicity in 1962, Wynne-Edwards stated that males displayed amongst themselves to assess their own density and decide which of them should breed and which should not (*Animal Dispersion in Relation to Social Behaviour*; Oliver

and Boyd, Edinburgh). The decisions are reached through competition for such prizes as a territory or a high rank in the social hierarchy. According to this thesis the fertilisation of ova is a secondary male role; the primary role is to ensure that the population is not allowed to exceed an optimum density above which habitat resources would be overstrained.

The late David Lack held firmly to the opinion that populations were kept below a level at which environmental damage would result by the action of predators or insect parasites (*Population Studies of Birds*; Clarendon Press, Oxford, 1966). In other words the size of the population is determined from without. Like Wynne-Edwards's, Lack's arguments are an extension of Nicholson's density-dependent control hypothesis (*J. anim. Ecol.*, 2, 132; 1933) inasmuch as there is a direct relationship between the severity of the controlling influence and the density of the population to be controlled. The displays which males put on apparently for other males, termed 'epideictic' by Wynne-Edwards, are seen by Lack to have nothing to do with a census but rather to have a sexual function in attracting females to males. In an early paper on black grouse (*Br. Birds*, 32, 290; 1939) he postulated that males displaying in groups attracted more hens than those displaying solitarily. He is thus critical of Wynne-Edwards's views that leks, traditional places for epideictic or nuptial displays, exist so that males can regulate the numbers of fe-

males fecundated and hence the population size.

Some long term studies of vertebrate leks are among the few studies of social behaviour in which observers have had the stamina to collect enough material to begin to assess these conflicting views.

The greater prairie chicken (*Tympanuchus cupido*) is a member of the grouse family which forms distinct leks. Robel and others (*Anim. Behav.*, 14, 328; 1966; *J. Wildl. Mgmt.*, 34, 306; 1970; *Auk*, 91, 75; 1970) have drawn attention to the fact that all matings take place at the lek. Between 1964 and 1969 there were few social upheavals at the chosen study leks and as a result 84% of the observed copulations were performed by dominant cocks. These also had the largest territories. This figure compares with 76% reported by Lumsden for dominant male sharptailed grouse *Res. rep. Ontario Dept Lands and Forests* No. 66, 1965 and 74% for dominant male sage grouse (Scott, *Auk*, 59, 477; 1942). During this long period of stability about 40 hens visited the lek each season of which, on average, 32 were mated. In 1970 three, and in 1971 two dominant cocks were removed from the lek and with them went the stability of the lek. The number of social interactions observed each morning, formerly running at 23, rose sharply to 109 and the number of females mated fell to three and two. Social unrest amongst the males clearly reduced the number of young produced by limiting

Miospore sequence from Scotland

Dinantian miospores from the Spilmersford Borehole in East Lothian, Scotland. The description of 45 specimens examined in a recently completed survey provides one of the first palynological reference sequences for the Lower Carboniferous in Scotland. 8, *Retusotriletes incohatus* Sullivan; 9 and 10, *Pulvinispora scolecophora* sp. nov.; 11, *Waltzispora planiangularata* Sullivan; 12, *Cyclogranisporites palaeophytus* sp. nov.; 13, *Raistrickia nigra* Love; 14, *Acoanthotriletes socraticus* sp. nov. In each case the magnification is 500X. Taken from the *Bulletin of the Geological Survey of Great Britain*, No. 45. (Her Majesty's Stationery Office, London, 1974.)

the number of females impregnated.

Elephant seals (*Mirounga angustirostris*) breed communally on selected small islands. Usually these are greatly overcrowded while other islands remain unburdened. In a six year study on Año Nuevo Island, California, Le Boeuf has focused attention on the small number of dominant males, usually fewer than one third of all resident males, which are responsible for the majority of copulations (*Am. Zool.* **14**, 163; 1974). Copulation frequency is directly related to success in competition between males for hierarchical accolade with alpha bulls being responsible for up to 49% of all matings. The Año Nuevo population is increasing, presumably due to subtle habitat changes, and with this increase is a decrease in the alphas' share of copulations. But there does seem to be some density dependent regulation in force. Le Boeuf in 1972 showed that a major source of pup mortality, up to 43% of all pups born, was the fighting of adult males (*Behaviour*, **41**, 1). Death to the pups was the result of being trampled upon by the bulls which weigh up to three tons. Crude though this mechanism may be, it is certainly effective. Social unrest among the males reduces the number of young produced by increasing infant mortality.

Some of the consequences of lek life in the Uganda kob antelope (*Adenota kob*) were reported in these columns a few weeks ago (**252**, 345; 1974). More than 15 years of study of the population in the Torro game reserve has revealed that there is a strong attachment to the home lek and adults of both sexes traditionally return home to breed (Buechner and Roth *Am Zool.*, **14**, 145; 1974). Only dominant males hold mating territories within the leks and, since clandestine matings are rare, they alone mate with females. There seems to be some limit to the number of territories in each lek, but what controls this is not known. Since rinderpest exterminated European cattle in this area kob populations have been increasing and a few additional leks are being formed. Population increase does not appear to be achieved by the establishment of additional territories within leks, but by the creation of additional leks.

Amid a welter of fascinating detail, these three studies reveal a couple of fundamental principles. First, they point out that Darwin's observations, *sensu stricto*, are incorrect because males fight not for females directly but for a conventional reward which itself confers the right to mate. Second, they show that social dominance is the key to conventional reward and hence to frequency of copulation. Additionally Robel's studies show that social stability between males is a major factor governing the number of females fecundated

and in Le Boeuf's study social interaction strongly influences infant survival.

Neither Lack's nor Wynne-Edwards's disquisitions can be proved or disproved by these studies although there is strong *prima facie* evidence that the behaviour of males has a regulatory function on the number of new individuals brought into the population. What has not been shown is whether leks serve primarily to census populations and their resources or to provide an attractive meeting, and mating, place. More long term studies may help to reveal the complications thrown in by such factors as overall population increase and so lead towards a correct interpretation of the function of leks. They may also, as a sideline help to indicate the area in which the regulation of human populations went awry.

Adapting to a chilly future

from Peter D. Moore

IF "The Threat of Ice" (see *Nature*, **252**, 216; 1974) is a real one, it may be salutary to learn how a variety of organisms adapt to cold. The adaptations of plants, which cannot migrate, must be physiological; they are also seasonal, in all but the most severe arctic and alpine climates. It has long been realised that the ability of many plants to tolerate cold varies with their recent temperature experiences (Levitt, *Handb. Pflanzenphysiol.*, **II**, 632; 1956); this knowledge has been used in the horticultural practice of frost hardening. Riedmüller-Schölm (*Flora, Jena*, **163**, 230; 1974) has recently examined the low temperature resistance of many Alaskan plants at monthly intervals

Another function for juvenile hormone

from our Insect Physiology correspondent

ONE attraction of the hormonal system of insects as a medium for the study of endocrinology has lain in the apparent simplicity of the range of hormones involved. As knowledge grows complexity increases. The diversity and subtlety of the effects of the juvenile hormone seem to militate against the formulation of any unitary theory of the control of metamorphosis. But a new factor has come to light in the course of studies by Nijhout and Williams (*J. exp. Biol.*, **61**, 481 and 493) on the tobacco hornworm *Manduca*. Throughout the early larval stages of *Manduca* there seems to be a continuing cycle of secretion of the brain hormone (the prothoracic-tropic hormone: PTTH) which induces the discharge of ecdysone by the prothoracic gland and of juvenile hormone from the corpus allatum, which ensures the maintenance of larval characters. But in the fifth or final larval stage the scene changes: feeding during this stage is more prolonged and when moulting does take place the larva suffers metamorphosis to the pupa.

One thing can be predicted from existing knowledge: the brain must not release PTTH while a large amount of juvenile hormone is circulating, or another larval stage will be produced. What is peculiar about the final larval stage, according to the results of Nijhout and Williams, is that the high titre of juvenile hormone inhibits release of PTTH by the brain. But when the larva reaches a certain weight (about 5 g) the corpora allata ceases

to secrete the juvenile hormone. Within about 24 h the juvenile hormone is cleared from the haemolymph and this results in the brain being rendered competent to release PTTH during the ensuing photoperiod. Growth continues for several days to give a final weight of about 8 g. The gut contents are then discharged and the behavioural and developmental changes that lead to pupation are set in train.

These observations provide an informative description of the hormonal changes during the last larval stage in Lepidoptera; and they illustrate a new function for the juvenile hormone. The failure of the normal arrest in juvenile hormone secretion is apparently responsible for the developmental arrest or diapause in the mature larvae of some Lepidoptera. Fukaya and Mitsuhashi and more recently Chippendale and Yin have stressed the importance of juvenile hormone in inducing larval dormancy. The onset and persistence of diapause in mature larvae can now be accounted for by a functional failure of the normal mechanism which inactivates the corpora allata of non-diapausing larvae.

The turning off of the corpus allatum secretion not only permits the morphological change of metamorphosis; it now seems to set in motion in caterpillars the endocrine events that lead to the moult itself. But what turns off the corpus allatum? Some environmental stimulus? Some proprioceptive stimulus? Or the passage of time?

through the course of a year and has found, rather predictably, that the highest degree of tolerance occurs in midwinter, though many species have a secondary peak of resistance at the end of winter, associated with the melting of snow cover. During these frost-hardy periods most plants examined (including angiosperms, gymnosperms, pteridophytes, bryophytes and lichens) were able to withstand a temperature of -80°C , in some cases for several days. Since the lowest observed temperature in the field during this time was -52°C the adaptations seem to be quite adequate for survival.

Perhaps surprisingly, maximum heat resistance was found to coincide with maximum frost tolerance in midwinter. For mosses these maxima ranged between 48 and 60°C , for vascular plants from 56 to 72°C and for lichens between 66 and 74°C . These figures exceed the published heat tolerance limits for plants of any climate, including tropical ones.

These data are all the more remarkable when one considers that many arctic and alpine plant species seem to be limited in their geographical distributions by high summer temperature (see Conolly and Dahl in *Studies in the Vegetational History of the British Isles*, edit. by Walker and West, page 159; Cambridge University Press, 1970). There are two points, however, which may help to explain the seeming anomaly. In the first place, high temperature resistance is very much less marked in summer than in winter; in the second place, temperature tolerance does not necessarily ensure that a plant would survive long periods at fairly high temperatures. Billings and Mooney (*Biol. Rev.*, **43**, 481; 1968) concluded that arctic/alpine plants have considerably higher respiration rates than do most temperate species. It could prove difficult for such plants to maintain a positive carbon balance at prolonged high temperatures.

The winter peak in high temperature tolerance must be regarded as a side-effect of the very physiological changes which provide low-temperature resistance. This has been observed previously, as has the drought resistance of such frost-hardy plants. The mechanism underlying these changes has recently been sought in cell membranes (see, for example, Raison, *Symp. Soc. exp. Biol.*, **27**, 485; 1973) particularly in mitochondria from fruit and vegetables. Wilson and Crawford (*J. exp. Bot.*, **25**, 121; 1974 and *New Phytol.*, **73**, 805; 1974) have now examined the level of unsaturated fatty acids in leaves during the development of low-temperature resistance. Using *Gossypium hirsutum* and *Phaseolus vulgaris* they demonstrated that the degree of unsaturation of the fatty acids associated with the

phospholipids (in the membranes of leaves) increased during the process of frost hardening. This was due in particular to increases in the percentage of linolenic acid in the phospholipids. It is suggested that the significance of this change is to lower the temperature at which a phase change occurs within these membranes from a liquid crystalline phase to a solid gel phase. A similar mechanism has also been suggested for poikilothermic animals. Such a membrane modification may have both a structural and a metabolic role by making membranes less susceptible to damage and allowing greater activity in certain enzymes.

Growth at 25°C also resulted in a higher degree of unsaturation in the phospholipid fatty acids, suggesting that this mechanism is also associated with high temperature tolerance. But tropical plants may have lost the capacity to increase the degree of fatty acid unsaturation in their phospholipids over short periods of time, thus rendering them sensitive to very low temperatures. As the next ice advance approaches, let us hope that we all have time to adapt.

Agglutination, proteolysis and cell division

from Robert Shields

WORKERS studying the control of cell proliferation have long been intrigued by the greatly decreased rate of DNA synthesis by normal cells in tissue culture when access to serum is restricted. When normal cultures reach their maximum (saturation) density the vast majority of the cells are in the G_1 phase of the cell cycle. Such cultures will undergo limited proliferation if the cells are treated with low doses of proteases or are given fresh serum. Under the same conditions tumour cells are not so subject to serum limitation; they will grow to far higher densities and are distributed throughout the cell cycle.

As tumour cells are more easily agglutinated by multivalent lectins such as concanavalin A (Con A) and confluent normal cells show transient increases in agglutinability when growth is stimulated with proteases, it was thought that exposure of lectin binding sites might regulate cell division. Experiments by Burger (*Nature*, **228**, 512; 1970) on transformed 3T3 cells with a preparation of trypsinised Con A (which was thought to be monovalent and so non-agglutinating) seemed to indicate that normal morphology and low saturation densities could be restored to the tumour cells by covering the Con A receptors on the cell surface.

A recent paper by Trowbridge and Hilborn (*Nature*, **250**, 304; 1974) has questioned these results; using the better characterised succinyl Con A (which is divalent) it was shown that covering the agglutination sites neither restored a low saturation density to transformed cells nor reduced DNA synthesis nor arrested cells in G_1 . These authors suggest that the restored saturation density seen by Burger may have been the result of cell death caused by the trypsinised lectin.

It is now realised that exposure of agglutination sites is similar in normal and transformed cells and that agglutinability requires rearrangement of these sites, which occurs more readily in transformed cells. It remained possible, however, that agglutinability *per se* was a sufficient condition for cell division until experiments with pronase demonstrated that density-restricted 3T3 cells could be made maximally agglutinable without cell division occurring (Glynn, Thrash and Cunningham, *Proc. natn. Acad. Sci. U.S.A.*, **70**, 2676; 1973).

A proteolytic activity on the transformed cell membrane seemed an attractive hypothesis in view of the similarities between transformed cells and protease-treated normal cells. The protease was thought to be responsible both for the high agglutinability and for an autocatalytic stimulation of division. Transformed cells were indeed found to have a greater proteolytic activity than their normal counterparts and moreover to have a proteolytic activity that converted plasminogen (present in the serum of the culture medium) to the protease plasmin. Reich and his co-workers (*J. exp. Med.*, **138**, 1056; 1973) showed that several of the characteristics of transformed cells such as altered morphology and the ability to grow in agar seemed to depend on plasmin activity. If these protease activities were really important in cell transformation the corollary was that inhibition of these proteases should cause phenotypic reversion of the transformed cells.

Once again early experiments looked promising. The growth of transformed cells was reduced and a lowered saturation was restored with protease inhibitors (Schnebli and Burger, *Proc. natn. Acad. Sci. U.S.A.*, **69**, 3825; 1972). With some protease inhibitors the cells showed a more normal morphology and had reduced agglutinability. But by this stage of the game it was becoming apparent that a lowered saturation density and morphological changes were poor evidence for restoration of density restriction of growth. A flurry of papers showed that inhibitors of plasminogen activation did not restore a low saturation density to transformed cells (Chou, Black and Roblin, *Nature*,

250, 739; 1974), and other protease inhibitors had no selective effect on tumour cell growth (McIlhinney and Hogan, *Biochem. biophys. Res. Commun.*, **60**, 348; 1974). Furthermore those that did arrested cells in the G₂ phase of the cell cycle (Collard and Smets, *Expl Cell Res.*, **86**, 75; 1974) and the cells continued to make DNA at their saturation densities (Schnebli and Haemmerli, *Nature*, **248**, 150; 1974). But these results only show that normal cell properties cannot be restored by certain protease inhibitors; they cannot rule out the possibility that some proteases are involved in maintaining the transformed state.

More antigens in hepatitis B

from Arie J. Zuckerman

AUSTRALIA ANTIGEN, now referred to as hepatitis B surface antigen in view of its close association with hepatitis B virus, was discovered as a lipoprotein which was immunologically distinct from normal low density lipoproteins. Examination of this antigen in the electron microscope revealed a remarkable morphological heterogeneity consisting of three principal virus-like particles (see Fig. 1). The main antigenic constituent is a small pleomorphic particle, 16–25 nm in diameter. A characteristic feature is the presence of tubular forms which vary greatly in length but with a constant diameter of 20 nm except for the bulbous swelling at one or both ends of the tubules. The third type of particle, the Dane particle, is also spheroidal measuring about 42 nm in diameter, with a 27 nm core, a 2 nm shell and an outer coat about 7 nm in thickness. There is now substantial evidence that the 42 nm particle is the human hepatitis B virus, the core being the nucleocapsid and the outer protein coat representing hepatitis B surface antigen. Immune electron microscopy and more recently various serological tests revealed the existence of two distinct antigen-antibody systems associated with the Dane particle; antibody to the core has a specificity entirely different from antibody against the outer protein coat. The morphological complexity of the particles associated with hepatitis B is matched by the complex antigenic reactivities of the outer coat. The antigenic constitution of the core is still under investigation.

The antigenic activity of the coat protein is associated with the small spherical particles, the tubular forms and the coat of the Dane particles. All these structures share a common group specific antigen (a) and the particles generally carry at least two sub-determinants: either d or y, which usually behave in a mutually exclusive

Fig. 1 Morphological appearance of hepatitis B antigen in serum showing three distinct entities: (1) Small pleomorphic spherical particles with a diameter of 16–25 nm. (2) Tubular forms. A terminal bulbous swelling is shown. (3) Double-shelled 42 nm Dane particles with a core and an outer coat. $\times 252,000$. (Electron micrograph reproduced with permission from A. J. Zuckerman *Hepatitis-Associated Antigen and Viruses*; North-Holland, 1972.)

manner although carried on the same antigen particle, and either w or r. There is evidence that the subtypes are the phenotypic expressions of distinct genotype variants of hepatitis B virus. Four principal phenotypes are currently recognised: adw, adr, ayw and ayr, but others are not precluded. Indeed complex permutations of these subdeterminants and new variants have been described, all apparently on the surface of the same physical particles. A remarkable geographical pattern of distribution of hepatitis B subtypes has emerged with four global zones, where there is an excess of one subtype, and regions where a mixture of subtypes is common (*Nature*, **247**, 2; 1974). These subtypes provide valuable epidemiological markers and offer a method for distinguishing one of several sources of infection. The surface antigenic reactivities do not seem to be associated with particular clinical forms of liver disease.

The above summary serves as an introduction to another antigen-antibody complex which is associated with molecules distinct from particles of hepatitis B antigen. Magnus and Espmark (*Acta path. microbiol. Scand.*, **B80**, 335; 1972) described a new distinct precipitating antigen, which they termed e, in sera containing hepatitis B surface antigen. This antigen differed markedly from the previously described determinants of the surface antigen. Paradoxically, antibody against e was found in serum specimens from healthy carriers of the surface antigen. The e antigen seemed to be somehow intimately associated with the pathogenesis of liver damage. Recently, Nielsen and col-

leagues (*Lancet*, **ii**, 913; 1974) reported their interesting observations on the e determinant. The e antigen was found by the simple immunodiffusion technique to be significantly more common in patients with chronic liver disease (chronic hepatitis and cirrhosis) with persistent hepatitis B antigenaemia than in patients with acute viral hepatitis. Furthermore, the e antigen seemed to be a valuable and important prognostic marker since progression to chronic liver disease was recorded by serial liver biopsies in 11 out of 19 consecutive patients with surface antigen-positive acute hepatitis associated with the e antigen. The clinical significance of the e antigen was supported by differences in the clinical, biochemical and histological findings between the patients with the e antigen and those without this antigen during the initial phase of viral hepatitis.

The exact nature of the e antigen is uncertain; it might be a host antigen produced by virus-infected liver cells or it might be related to another antigenic constituent of the infecting virus, perhaps the core of the Dane particle. Preliminary results from Nielsen's laboratory showed a large number of Dane particles in serum samples containing the e antigen, whereas e antibodies have previously been found in healthy carriers of the surface antigen in whom Dane particles had not been demonstrated. Though the precise relationship of e to hepatitis B virus is yet to be established, it is evident that the antigenic complexity of this unique infectious agent will continue to unravel.

Position effects in gene inactivation

from Benjamin Lewin

GENES translocated to positions close to heterochromatin seem in many species to become inactivated. Among the earlier observations were those made in *Drosophila* where, for example, some of the facets of the eye are white instead of red in heterozygotes in which the dominant gene has been transferred to a site adjacent to heterochromatin (see Lewis, *Adv. Genet.*, **3**, 75–115; 1950). It has since become apparent that this position effect variegation takes place in *Drosophila* when a wild type allele is placed in *cis* alignment with heterochromatin, with a recessive allele carried on the normal homologue; the wild type allele is inactivated in some cells, thus causing the variegation. The probability that a locus will be subject to this effect depends upon its relationship to the site of translocation; the closer it lies to heterochromatin, the more likely it is to be inactivated. Inactivation is de-

terminated during larval embryogenesis.

Although similar situations arise in the mouse, the rearrangements that cause the variegation always involve X-autosome translocations; in female mammals, one of the two X chromosomes, chosen at random, is inactivated in each somatic cell at any early stage of development, and the position effect can thus be shown only in those cells in which the rearranged X chromosome is inactivated to form heterochromatin. X inactivation occurs when the number of cells in the embryo is small, probably about 60 (Ohno *et al.*, *Cell*, **1**, 175-191; 1974; for review see Lewin, *Nature*, **249**, 9-11; 1974). This generates clones of cells in which only either the maternal or the paternal X chromosome is active, giving rise to variegation in the adult for any X-linked genes for which it is heterozygous. Thus although in an earlier study Cattanaach, Wolfe and Lyon (*Genet. Res.*, **19**, 213-228; 1972) showed that the variegated coats of mice heterozygous for an X-autosome translocation display a pattern similar to that of chimaeric animals, the conclusion that the autosomal locus on the translocated X chromosome is inactivated in early development does not distinguish between random X inactivation and position effect variegation. An analysis which allows these phenomena to be resolved is now reported by Cattanaach (*Genet. Res.*, **23**, 291-306; 1974).

The heterozygotes used in this study possess an X chromosome, X^T , that carries part of autosome 7; an X chromosome, X^N , that is normal; and a normal set of autosomes. The insertion within X^T carries the wild type genes $+^o$ and $+^p$ for coat colour; the normal copies of autosome 7 carry the recessive alleles c (albino) or its alternative c^{ch} (chinchilla) and p (pink-eye). Expression of the autosomal recessive coat colour alleles occurs in cells in which the insertion within X^T has been inactivated; coat colour genes are expressed by the melanocytes, which reach their ultimate positions in the hair follicles by migrating laterally down the foetal body. Each clone of melanocytes gives rise to a band across one side of the mouse coat; the clarity of these bands was enhanced in these experiments by use of the gene s , recessive spotting, which appears to reduce intermingling between cells of adjacent bands. Three sets of experiments were performed with this system.

In animals that suffered random inactivation, expression of the p and c^{ch} genes was followed in the bands. Three types of band were observed: $+^p +^o$ (wild type colour); $p c^{ch}$ (white); and $+^p c^{ch}$ (brown). The $+^p +^o$ bands are derived from cells in which the translocation chromosome X^T was active;

the $p c^{ch}$ bands represent cells in which X^T was inactive and both the $+^p$ and $+^o$ alleles on its insertion were inactivated. This confirms the clonal nature of the lines descended from cells in which either X^N or X^T respectively were inactivated. The third band, $+^p c^{ch}$, however, is derived from cells in which X^T was inactivated; but although the inactivation extended to $+^o$ it did not include $+^p$, which remained active. Since the $+^o$ locus is closer to the material of the X chromosome than is the $+^p$ locus, this is in accord with earlier experiments that showed that inactivation spreads sequentially from the X chromosome into the inserted autosomal material. By obtaining variegation of one of the inserted genes relative to the other, these results demonstrate that position effect variegation in the mouse is clonal and must have occurred early in development, between the time of X inactivation and the colonisation by melanocytes.

The animals used in these experiments had the genotype Xce^b/Xce^b , where Xce is a locus on the X chromosome which can influence the usually random pattern of inactivation; the Xce^b allele (previously known as Xce^1) permits random inactivation. But the Xce^a allele (previously described as Xce^c) causes the X chromosome carrying it to be inactivated more frequently in Xce^a/Xce^b heterozygotes; and in experiments in which the X^T chromosome carried the Xce^a allele (its normal homologue carrying Xce^b), the frequency of $+^p c^{ch}$ bands was increased, for the number of cells with $+^p$ active and $+^o$ inactivated was increased.

In the second set of experiments, random X inactivation was suppressed by using an X chromosome which carried Searle's translocation; this X is never inactivated, so it is the genes carried by the other X chromosome, in these experiments X^T , that fail to be expressed. But mice which carry $+^o$ on X^T and carry c on both copies of autosome 7 may still display some variegation for the c phenotype. Thus although X^T is inactive, the $+^o$ gene on the inserted autosome segment can still be expressed, albeit at frequencies less than 5%. The pigmented areas are always small—much smaller than whole bands. When the autosomes of such mice carry p as well as c , extensive pigmentation occurs in the production of $+^p c^{ch}$ regions, in which $+^p$ must be active in the inactivated X^T chromosome, although its $+^o$ gene remains inactive. The $+^p c^{ch}$ regions may occupy whole bands; this suggests that only genetic events are implicated in their establishment, excluding alternative explanations such as cell selection. By extension, this argument implies that the small pigmented areas in the mice where only the c locus is the sub-

ject of variegation also must have a genetic origin; so these must be derived either by late determination or by a reversal of an earlier inactivation.

In the third series of experiments, animals whose variegation had been examined were kept for up to 18 months and scrutinised for changes in coat colour as ageing took place. It has been observed previously that in general c areas uniformly darken with age. This suggests that a reversal of inactivation takes place with time, leading to expression of the $+^o$ gene on X^T . When the $p c^{ch}$ areas of the mice used in Cattanaach's experiments were examined, he found that they first turn the brown colour characteristic of $+^p c^{ch}$ cells and then turn the black colour characteristic of $+^p +^o$ cells. This suggests that the inactivating influence along the autosome insertion within the X chromosome gradually retreats, causing sequential reactivation.

From these results, Cattanaach proposes an alternative to the previously proposed explanations of position effect variegation in the mouse. The variegation has usually been attributed to a sequential inactivation proceeding along the translocated autosomal region from the X chromosome. This might involve structural changes, or, as has been suggested for *Drosophila*, the addition of suppressor molecules to the inactivated regions. Given that reactivation is responsible for events occurring later in development, however, Cattanaach argues that perhaps only one mechanism is responsible for all variegation, irrespective of whether it takes place early or late. Thus after inactivation of the translocated autosome (possibly still to a limited extent), a progressive reactivation takes place with time from the point most distant from the site of translocation; this must vary in rate in different cells. If reactivation at any locus occurs at an early stage, an active gene will be clonally inherited; although the descendants of this cell all will possess this activity, subclones may be generated as progressive reactivation applies to other loci. This model has the advantage that the position effect can be explained by a single mechanism operating at all stages of development, in contrast with models where stability of the inactivated autosome region is implied and for which an alternative model must be invoked to explain reactivation. Since there is no suggestion that the reactivation applies to genes of the X chromosome itself, the model draws a clear distinction between the sex heterochromatin and the autosomal insertion, although no implications are made about the molecular mechanisms that may maintain the inactive X but progressively fail to inactivate the autosomal region.

Unconformities in the sediments of the Indian Ocean

Thomas A. Davies & Oscar E. Weser

Deep Sea Drilling Project, Scripps Institution of Oceanography, La Jolla, California

Bruce P. Luyendyk

Robert B. Kidd*

Institute of Oceanographic Sciences, Wormley, Surrey, UK

Deep sea drilling in the Indian Ocean has revealed unconformities of oceanwide significance. The unconformities are of Oligocene, early Tertiary and late Cretaceous age and can be explained as a consequence of climatic events in Antarctica and subsequent variations in the circulation pattern of the whole Indian Ocean.

UNTIL recently it was believed that sedimentation in the deep oceans is essentially continuous. One of the more unexpected results of the Deep Sea Drilling Project (DSDP) has been the discovery of large gaps in the sedimentary record at many sites. Major hiatuses of regional significance have now been identified in the Atlantic, Caribbean, Pacific, Antarctic and Indian Oceans. Data from sites drilled on DSDP Legs 22-27 and part of 28 (Fig. 1, refs 1-7) show that in the Indian Ocean gaps in the sedimentary record have been encountered in a broad spectrum of terrigenous, pelagic, biogenic and volcanogenic sediments encompassing late Mesozoic and Cainozoic time. The hiatuses were encountered at more than half the 48 sites and are developed on a wide variety of topographic features over a broad range of depths. They seem to show temporal groupings centred in the Oligocene, early Tertiary, and late Cretaceous.

Here we use the term unconformity to refer to a significant gap (demonstrated or inferred) in the stratigraphic record (disconformity or paraconformity). Unconformities are considered to represent active erosion or complete non-deposition of sediment. At many sites undated intervals were encountered, barren of microfossils, usually with a lithology of detrital or pelagic clay accompanied by zeolites and other indicators of extremely slow sedimentation. These intervals, which may be considered dissolution facies, represent slow sediment accumulation beneath the carbonate compensation depth (CCD). They may or may not contain unconformities, but this cannot easily be resolved because of the lack of biostratigraphic control. There is indirect evidence that in many cases the undated intervals do encompass unconformities.

The descriptions of unconformities from the results of some of the earlier legs of the drilling programme have been somewhat equivocal because of the often large unsampled intervals in the cores. Fortunately, in the Indian Ocean programme,

continuous coring or instances of greater than 50% coring were frequent. So we have considerably more confidence in recognising unconformities and in determining their extent. The Oligocene unconformity can be recognised with certainty at 15 of the 33 sites sampling that time interval and there is good evidence for its presence at 11 further sites making a total of 26 out of 33 sites. Corresponding figures for the early Tertiary and late Cretaceous unconformities are 18, maybe 27, out of 30 sites, and 9, maybe 13, out of 13 sites, respectively. It is clear, therefore, that these unconformities are of oceanwide significance. We believe that they can be explained as the consequence of climatic events in Antarctica and subsequent variations in the circulation pattern of the whole Indian Ocean.

Stratigraphic record in the Indian Ocean

Western Indian Ocean. In Fig. 2 the stratigraphic intervals recorded at sites in the western Indian Ocean are shown projected into a north-south line (locations in Fig. 1). Unconformities and/or undated intervals are shown centred on the Oligocene and the early Tertiary (or latest Cretaceous). The crust in the western Indian Ocean is generally younger than the eastern basin, with most western sites being no older than latest late Cretaceous. Consequently, a separate late Cretaceous hiatus is recognisable at only a few sites. True unconformities were encountered at 11 sites. Undated intervals, generally represented by a dissolution facies of zeolitic clay, are equally common. In many cases, such as sites 248 and 250, the sediments in these intervals are thin relative to those above or below, implying that the undated intervals do contain true unconformities. Local unconformities are indicated since the late Miocene at Site 240 in the Somali Basin and in the Pliocene at Site 249 atop the Mozambique Plateau, as well as at sites in the north-western basins. The maximum duration of the Oligocene hiatus is from the late Cretaceous to the early or middle Miocene (Site 249), indicating that the physical causes of the disconformities and dissolution facies ceased operating in the early/middle Miocene but could have been initiated at any time prior to this back to the late Cretaceous. The time-span of the early Tertiary hiatus extends from at least the Maestrichtian (Site 248) to late Eocene (Site 239).

Generally it seems that the cause of these unconformities is pervasive throughout the water column since both shallow and deep sea floor have been affected.

* Present address: Deep Sea Drilling Project, Scripps Institution of Oceanography, La Jolla, California.

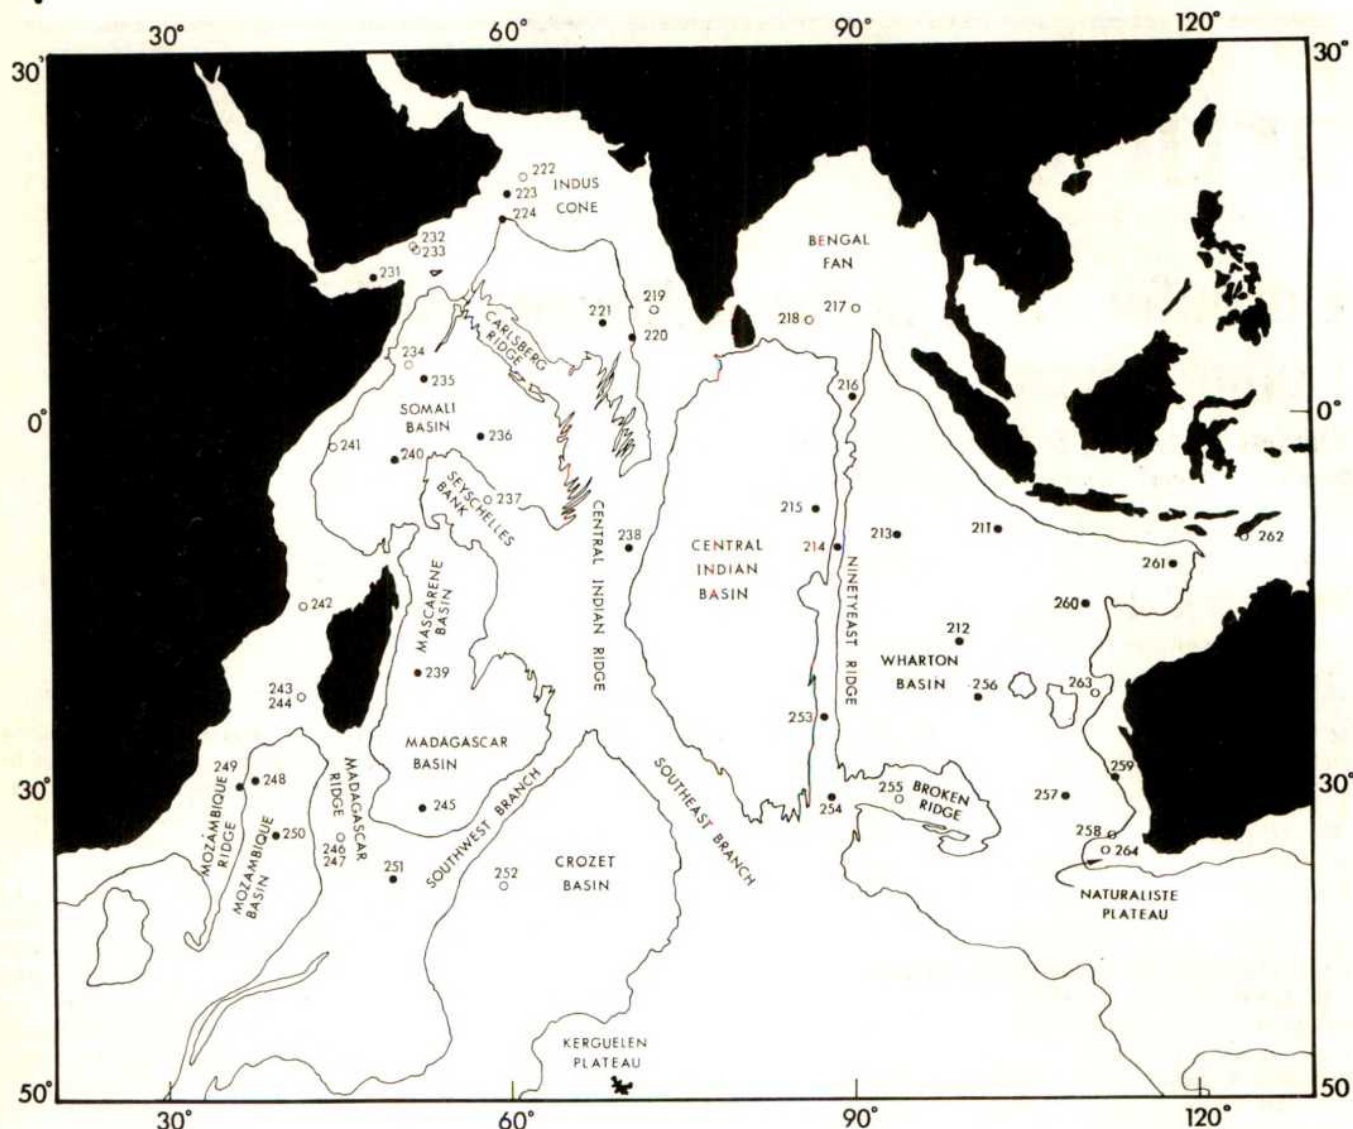

Fig. 1 Deep Sea Drilling Project sites in the Indian Ocean. ●, Sites which reached basement; ○, other sites. The principal physiographic features are defined by the 4,000 m contour.

Eastern Indian Ocean. Data from sites in the eastern Indian Ocean are interpreted to show hiatuses centred on the Oligocene, early Tertiary and/or late Cretaceous (Fig. 3). The upper limit of the Oligocene hiatus in Figure 3 is in the late Miocene or Pliocene (Sites 264, 258, 261, 215). The limits of the earlier hiatuses are not well defined but we interpret the upper limit of the early Tertiary hiatus to be in the middle Eocene (Site 216, 217) and the limit of the Cretaceous hiatus may be as young as late Palaeocene (Site 264).

Unconformities are again present in a variety of bathymetric features. They are found in the shallow sites on the Naturaliste Plateau, Ninetyeast Ridge and Broken Ridge and at deep sites such as 213, 215, 259 and 263. At the deeper sites, undated intervals—which may or may not include unconformities—are common.

Comparing Figs 2 and 3 we see that the hiatus centred on the Oligocene ends in the middle Miocene in the west and in the late Miocene/Pliocene in the east. On the Ninetyeast Ridge, the Oligocene hiatus ends in the late Oligocene, suggesting that if the same physical cause is responsible for both the shallow and deep hiatuses, it ceased functioning in the shallow regions first. The early Tertiary unconformity ends in the early Eocene in the west and middle Eocene in the east. The causes of both these unconformities seem to have ceased operating sooner in the west than in the east.

Regional extent of the Cainozoic hiatuses

The danger of regionalising these observed hiatuses cannot be overemphasised, considering our imperfect knowledge of the history of the local sedimentation regimes at each site. Nevertheless it is instructive to try.

In Fig. 4 we have plotted Oligocene and older DSDP sites from Legs 21 to 28 on a late Oligocene tectonic reconstruction. The extent of the Oligocene hiatus is indicated by the shaded regions. The hiatus is present at both shallow and deep sites whereas a complete Oligocene section (apparent) was recovered in the north-west Indian Ocean at shallower sites near the ancient ridge crest and nearer to the palaeoequator. Figure 4 shows that the western Pacific sites of DSDP Leg 21 exhibit the same hiatus. Kennett *et al.*⁸ described this hiatus as a disconformity found at various depths between 1,400 and 4,500 m. It seems to end in the middle Miocene, about the same time as in the western Indian Ocean. Kennett *et al.* pointed out that Oligocene unconformities are also found in southern Australia, New Guinea and parts of New Zealand⁹⁻¹¹. Carter and Landis¹² described the south Australian unconformity as a paraconformity below shelf limestones of early Miocene age. Oligocene hiatuses are not generally found in the central Pacific. The south central Pacific DSDP Leg 8 results show a hiatus near the late Eocene/early Oligocene but the hiatus itself is marked by calcareous ooze with very high ^{137}Cs concentrations.

Fig. 2 Stratigraphic section sampled at sites in the western Indian Ocean. Sites 243 and 244 are omitted since no cores were recovered from these sites. Basement ages at Sites 248 and 249 were determined radiometrically⁴.

rates¹⁴. High calcareous sedimentation was also seen in the sediments sampled on DSDP Leg 3 in the South Atlantic¹⁵, where the Oligocene is represented by two chalk ooze formations. Clearly, erosion and/or non-deposition and dissolution in the Indian Ocean and south-west Pacific during the Oligocene was contemporaneous with high carbonate deposition in other oceans of the world.

In Fig. 5 we have plotted Indian Ocean and south-western Pacific DSDP sites on an early Eocene reconstruction. The early Tertiary hiatus is more difficult to regionalise because it is often obscured by the overlying Oligocene hiatus and at many sites the oldest sediments recovered were younger than Eocene. But certain patterns seem similar to those of the Oligocene data; these include uninterrupted sedimentation in the north-west, unconformities on shallow structures such as the Ninetyeast Ridge, and a well developed hiatus in southerly latitudes. The similarity in the regional patterns of the early Tertiary and Oligocene hiatuses implies that they may be due to similar causes.

The early Tertiary hiatus is documented in the central Pacific by DSDP Leg 17 results¹⁶. This hiatus is a disconformity which ends in the middle Eocene in both shallow (2,300 m, Site 171) and deep (5,500 m, Site 164) sites. The central Pacific hiatus ends at the same time as the early Tertiary hiatus on the Ninetyeast Ridge. Leg 21 results also show a hiatus ending in the middle Eocene in the southwest Pacific⁸ (Fig. 5). In the South Atlantic, the early Tertiary sequence is complete¹⁵.

Late Cretaceous sediments have not often been sampled by DSDP, but in the central Pacific some Leg 17 results indicate an unconformity ending in the Campanian as in the Indian Ocean.

It seems, therefore, that regional hiatuses in the Cretaceous and early Tertiary in the Indian Ocean are closely allied with contemporaneous ones in the central and south-west Pacific. The Oligocene hiatus in the Indian Ocean and south-west Pacific, however, occurred at the same time as high calcareous sedimentation in the central Pacific and South Atlantic.

Fig. 3 Stratigraphic section sampled at sites in the eastern Indian Ocean. Ridge and plateau sites (right) are separated from the basin sites (left). The basement age for Site 212 is derived from geophysical evidence¹⁷.

Fig. 4 DSDP sites plotted on an early Oligocene reconstruction of the Indian Ocean²⁶. Open circles represent sites where the sedimentary section is complete; solid circles where there is a proven unconformity, and half circles where there is an undated interval or an inferred unconformity. The shading indicates the extent of the Oligocene unconformity; crosshatching showing the extent of the proven unconformity.

Fig. 5 DSDP sites plotted on a middle Eocene reconstruction of the Indian Ocean²⁶. ○, sites where the sedimentary section is complete; ●, sites where there is a proven early Tertiary unconformity; half circles where there is an undated interval or an inferred unconformity; ▲, sites where an early Tertiary unconformity cannot be separated from the overlying Oligocene unconformity. The shading indicates the probable extent of the early Tertiary unconformity; crosshatching showing the extent of the proven unconformity.

Significance of the hiatuses

Attempts to explain the cause or causes of these hiatuses must consider numerous variables, including tectonism and continental drift, world climate, oceanic productivity, and oceanic circulation and oceanic chemistry, all of which are inter-related in a complex way. In perhaps the simplest cases (the early Tertiary unconformity on Broken Ridge (Site 255) and those near Owen Ridge (Sites 223 and 224)) the unconformities are clearly the result of tectonic uplift and subsequent erosion^{2,17}. On the other hand Kent¹⁸ has drawn attention to the fact that hiatuses in the sediments of the south-west Indian Ocean, while seemingly corresponding to tectonic events on land, are more likely to have been the results of variations in oceanic circulation and sediment supply rather than being directly attributable to tectonic events. The same may be said of the gaps found in the sedimentary record on the Naturaliste Plateau; for the sites in the deep basins remote from tectonic activity the links between hiatuses and such activity must be even more tenuous, if not non-existent. Even if we exclude locations for which there is a clear case for a tectonic origin for the unconformities, we are still left with the task of explaining the occurrence of oceanwide gaps in the sedimentary record. Recognising the limited data available and the complexity of the problem, we will limit our speculations to the Oligocene and early Tertiary hiatuses.

The following observations might be considered facts regarding these hiatuses which require explanation:

- (1) Both hiatuses are expressed over a wide depth range.
- (2) Well developed unconformities appear in the western Indian Ocean and south-west Pacific whereas undated intervals, probably containing unconformities, are more common in the eastern Indian Ocean.
- (3) The early Tertiary and Oligocene hiatuses have similar regional extent in the Indian Ocean and south-west Pacific.
- (4) The Oligocene hiatus is not found in the central Pacific as is the early Tertiary hiatus.
- (5) The Oligocene unconformity in the Indian Ocean and south-west Pacific occurs in concert with high calcareous sedimentation rates in the South Atlantic and central Pacific.

In our discussion we use the following model for hiatus formation in the deep sea. True unconformities are due to erosion or non-deposition caused by vigorous surface and/or deep ocean currents. The fact that the hiatuses in question cover such a wide depth range indicates that both deep and surface circulation have been involved. Dissolution facies are

formed below the CCD where calcareous material is dissolved. The CCD is the level where dissolution of carbonate by cold, under-saturated bottom waters balances carbonate supply from surface waters. The CCD may be moved shallower by a decrease in regional productivity, removal of oceanic carbonate by precipitation on shelf areas, or an increase in the amount and rate of supply of cold bottom waters, all of which result in an increase in the under-saturation of bottom waters¹⁹.

Bottom water in the Southern Hemisphere forms in the Antarctic shelf regions, notably in the Ross and Weddell Seas²⁰. Weddell Sea water in part flows east into the south-western regions of the Indian Ocean where it behaves as a western boundary undercurrent. Bottom water also drifts north through fracture zones in the south-east Indian Ridge, where it may be joined by Ross Sea water flowing west between Australia and Antarctica, to pass through the gap between Naturaliste Plateau and Broken Ridge into the Wharton Basin²⁰. This pattern of circulation seems to mirror the regional development of the Oligocene hiatus and possibly the early Tertiary one as well, and would explain why the hiatuses are more definitely expressed in the western ocean regions. Tectonic and climatic events in the Antarctic region are therefore important.

An important event in the late Cretaceous was the rifting of New Zealand from Antarctica and the opening of the Ross Sea²¹. Shortly after this, in the early Eocene or before, climatic deterioration and glacial conditions occurred in Antarctica²². This combination of events may have led to the formation of substantial amounts of 'aggressive', erosive Antarctic Bottom Water, Ross Sea water entering the central and south-west Pacific to erode and dissolve sediments and Weddell Sea water spreading eastwards between Africa and Antarctica into the western basins and through the gap between Broken Ridge and Naturaliste Plateau into the Wharton Basin. Surface circulation was intensified as a result of climatic cooling and perhaps increased storminess. This could explain the occurrence of well-defined unconformities at many of the shallow sites contemporaneous with undated intervals and unconformities in the deep basins. If surface productivity and faunal diversity were also decreasing during the early Tertiary, as is widely believed, these would serve to enhance shoaling of the CCD and result in the extensive formation of dissolution facies.

A similar story can be constructed for the Oligocene hiatus since climate deterioration and late Oligocene glaciation are

probable for Antarctica at that time²². It is curious that the Oligocene hiatus is not found in the central Pacific. Post-Oligocene erosion is found in the Samoan gap, the bottom water conduit into the central Pacific²³. Dissolution of great quantities of carbonate in the Indian Ocean and south-west Pacific in the Oligocene is possibly related to the contemporaneous high carbonate sedimentation elsewhere in the Pacific and Atlantic as the ocean responded to the need to maintain a chemical balance. Also, it is possible that at this time Ross Sea water was confined to the south-west Pacific by Melanesia and thus had relatively little influence in the regions farther north.

Between the late early Eocene and the middle of the Oligocene climatic conditions in Antarctica were probably a little warmer. This was sufficient to reduce the supply of Antarctic Bottom Water, encourage increased surface productivity, and diminish the intensity of current activity to the point where sedimentation could resume. The Oligocene hiatus was brought to a close by the gradual establishment of the present pattern of circum-Antarctic flow sometime near the end of the Oligocene²⁴. This again reduced the inhibiting influence of Antarctic Bottom Water on sedimentation in the ocean basins farther north, since a substantial proportion of the Antarctic Bottom Water was diverted into circumpolar flow and proportionately less found its way into the basins.

This attempt to attribute regional patterns of unconformities to climatic events in Antarctica is incomplete in several respects. First, the present day pattern of Antarctic Bottom Water circulation and its effects on deep ocean sedimentation are not entirely clear, much less these effects 60 Myr ago. Palaeobathymetry models would be helpful, as would further hydrographic stations and piston cores in the Indian Ocean. Second, present understanding of what effect Antarctic glaciation had on ocean surface water movements is equally vague. These currents have probably contributed to forming the hiatuses at shallow sites. We recommend experimental and analytical study of these currents taking into account continental dispersion and palaeowinds²⁵. Finally, more precise evaluations of the stratigraphy at each site will result in a more refined picture of palaeocirculation patterns.

W. H. Berger, J. V. Gardner, T. C. Moore and E. L. Winterer reviewed the manuscript and made suggestions. The DSDP is supported by the National Science Foundation.

Structure and assembly of filamentous bacterial viruses

D. A. Marvin & E. J. Wachtel

Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, Connecticut 06520

The protein coat of filamentous bacterial viruses is constructed from segments of a helix that extend in an axial direction, and overlap each other like shingles or fish scales to form a hollow cylindrical shell. This hollow shell contains the viral DNA.

THE protein coat of filamentous bacterial viruses^{1,2} is rich in α helix. This has enabled us to develop a model for the virus structure. We have used low resolution X-ray diffraction data to define the general arrangement of α helices, followed by molecular model building to define atomic positions. Our model

has implications for the morphogenesis of these viruses, and also for the structure of linear assemblies of proteins in general.

Filamentous bacterial viruses consist of linear assemblies of coat protein subunits encapsulating single-stranded, circular DNA. The virions measure about 60 Å in diameter by 10,000 to 20,000 Å long, depending on the strain, and contain no more than 12% by weight of DNA. The major coat protein in all strains comprises about 99% of the viral protein, has a molecular weight of about 5,000, and is largely α helical. Their relative simplicity and the relatively high quality of their X-ray diffraction patterns makes these viruses uniquely valuable models for the study of the molecular structure of fibrous proteins and

Fig. 1 Schematic illustration of some features of the filamentous bacterial virus life cycle. Successive stages are drawn counter-clockwise around the bacterium, although it is unlikely that all stages would be found at once in any given bacterium. The entire illustration is consistent with current data, but some features are less solidly supported by experiment than others. *a*, The virus attaches to the Gram-negative bacterium by means of a minor coat protein, the A protein (the bacterial attachment site is the sex-pilus for some strains² but not others^{28,29}). *b*, The viral DNA and A protein³⁰ enter the bacterium, leaving the major coat protein at the plasma membrane²⁷. *c*, The viral DNA is converted to a duplex form, that replicates to give several hundred progeny duplexes. Viral DNA replication may require the presence of viral coat protein in the membrane³¹, perhaps to create a new site for DNA replication³². *d*, The progeny duplex spins off a single-stranded tail that is coated with the protein product of viral gene 5. *e*, The DNA is closed to give a circular DNA molecule in a linear DNA-gene 5 protein complex³³. *f*, The viral DNA passes out through the bacterial envelope. The gene 5 protein is displaced from the DNA by coat protein that had previously been deposited at the plasma membrane²⁵. The completed virion is released from the bacterium without lysing or otherwise killing the bacterium³⁴. Inhibition of viral assembly in contrast does kill the host in a process involving the gene 5 protein³⁵. More complete citations of the earlier literature are given in ref. 2.

nucleoproteins. In addition, their unusual life cycle (Fig. 1) makes them interesting systems for the study of dynamic molecular interactions such as the displacement of one protein by another from a nucleoprotein complex, and the transport of macromolecules across membranes.

Structures of these viruses

Concentrated gels of filamentous bacterial virus can be oriented in fibres for X-ray diffraction studies³. Two classes of diffraction pattern, differing in detail, were found during a survey of various strains carried out in this laboratory^{4,5}. The class I pattern is given by the fd, f1, M13, If1, and IKe strains⁴; the class II pattern is given by the Pf1 and Xf strains⁵. The class II pattern is simpler to interpret, and has therefore been analysed in more detail⁶. The position of diffracted intensity on the pattern indicates⁶ that the protein subunits in the virus are arranged on a helix of pitch ~ 15 Å, with 4.4 subunits in one pitch length of the helix (Fig. 2). The relative magnitudes of diffracted intensity indicate that the diffracting material at each surface lattice point is elongated into a rod that makes an angle of about 20° with the helix axis, and also tilts from large to small radius in the virus. The orientation determined for the rods of electron density is such that rods originating on one turn of the helix interdigitate between rods originating on the next turn.

Spectroscopic measurements^{7,8} show that the α -helix content

of the coat protein approaches 100%. We have therefore assumed that the rods of electron density found from qualitative analysis of the X-ray pattern can be considered as single rods of α -helical protein measuring 10 Å by 70 Å, the dimensions of an α helix with molecular weight 5,000, and have used model-building techniques for further analysis of the structure. The α helix was represented in initial models by a row of points distributed on a curve 70 Å long. The Fourier transform⁶ of this repeat unit in the virus helix was calculated for various orientations and curvatures of the row, and compared with the class II diffraction pattern. The results of many trial calculations confirmed the conclusions about orientation of rods of electron density that were derived from direct analysis of the diffraction pattern. For the next stage in our model building, the row of points was replaced by a 70 Å polyalanine α helix. We generated the co-ordinates of atoms in this α helix by extending Crick's equation for the co-ordinates of a coiled coil⁹ to allow for a change in radius of the α helix in the major helix frame. Scattering factors of atoms were modified as described by Wilkins and coworkers¹⁰ to take into account the background electron density due to water and low density protein sidechains¹¹. The contribution of the DNA to the calculated diffraction was ignored at this stage.

Both intrachain and interchain stereochemistry were included as further constraints on the model. The intrachain stereochemistry of the α -helix rod was refined by fitting a stereochemically perfect polypeptide chain to the rough guide coordinates generated for the curved α helix, using the computer program developed by Diamond¹². The Ramachandran angles were $110^\circ < \phi < 133^\circ$ and $123^\circ < \psi < 149^\circ$ over the length of the refined α helix, and internal hydrogen bond lengths of the refined structure were also within the permissible range for α helix¹³. The interchain stereochemistry (the distance between

Fig. 2 Surface lattice of the class II helix. The lattice shows the 22 equivalent points in a 77 Å section of the virus helix, projected on to a cylindrical surface coaxial with the virus, which is then opened out flat and viewed from the outside of the helix. The dashed line shows the ~ 15 Å pitch of the virus helix. There are 22 units in 5 turns or 4.4 units per turn⁶. These helix parameters define the order of the Bessel functions predicted on each layer line of the helix diffraction pattern. In particular, for layer lines $l = 1, 2$ and 3 , the lowest order Bessel functions are those with order $|n| = 9, 4$ and 5 , respectively. The sign associated with $|n| = 5$ and 9 is opposite to that associated with $|n| = 4$. The sense of the helices with (n, l) indices $(5, 3)$ and $(9, 1)$ must be the same as that of the ~ 15 Å virus helix (they are shown as left-handed in this figure), but the absolute sense is not defined by the X-ray data. The fact that intensity is stronger on $l = 1$ and 3 than on $l = 2$ indicates that rods of electron density have the same sense as the ~ 15 Å helix. These rods of electron density roughly follow the $(14, 4)$ helix. The maxima of intensity on both $l = 1$ and $l = 3$ are observed at 0.1 Å⁻¹ along the layer lines, even though the predicted Bessel function orders are quite different for these two layer lines. This indicates that the rods of electron density tilt from large to small radius as well as slewing around the virus⁵.

Fig. 3 Comparison of the calculated Fourier transform of the class II protein model with the observed diffraction amplitudes. Continuous diffraction on non-equatorial layer lines was measured^{13,15} on a diffraction pattern of Pf1 taken at 98% relative humidity by Dr R. L. Wiseman⁵ (film No. 2036). The cylindrically averaged Fourier transform was calculated for a repeat unit consisting of a 46-residue stretch of polyalanine α helix the axis of which roughly follows a segment of a conchospiral with $\alpha = -21^\circ$ and $\gamma = 11.5^\circ$ between 14 Å and 26 Å radius. This repeat unit was placed in a left-handed helix having 22 units in 5 turns in an axial repeat $c = 77$ Å. Over most of the region of close contact between neighbouring α helices, distances between the α -helix axes were 10 ± 1 Å and crossing angles between the axes were $9-12^\circ$. Observed amplitudes are solid lines; calculated amplitudes are dashed lines. The rectangular box on $l = 2$ represents integrated intensity for which the shape could not be determined. Analysis of the equator is discussed in ref. 15.

neighbouring α helices and the angle at which the axes of neighbouring helices cross each other) was such that sidechains on one α helix could fit into the space between sidechains on its neighbours in knobs-into-holes packing⁹. Only α helices whose axes follow a left-handed helical path can form satisfactory knobs-into-holes packing, indicating that the sense of the ~ 15 Å virus helix is also left-handed (Fig. 2).

The resolution of the X-ray data is not sufficient to define the positions of specific sidechains, but reasonable assumptions about the orientation of the protein molecule can be made on general chemical grounds. The acidic N-terminal end of the Pf1 protein was placed at the outer radius of the virus, and the basic C-terminal end at the inner radius, as first suggested for fd⁷. The α helix was then rotated about its own axis so that arginine-44 and lysine-45 were directed inwards, towards the virus core; the acidic residues were directed outwards at the virus surface; and most of the hydrophobic residues were involved in contacts with neighbours¹⁴.

There are narrow limits on the range of models that are consistent with all these stereochemical constraints and yet give calculated transforms similar to the observed. The observed and calculated transforms for the current best model are compared in Fig. 3. The model is illustrated in Figs 4 and 5.

Fourier analysis of the equatorial intensity (which gives information about the electron density projected down the long

axis of the virion) shows that the DNA occupies a central core surrounded by a shell of protein, with virtually no interpenetration of DNA and protein¹⁵. X-ray diffraction and chemical evidence, however, are insufficient for a detailed model of the DNA to be built at this time.

Symmetry and perturbation

An overlapping or shingled arrangement of axially elongated protein subunits as found for filamentous bacterial viruses is a stable and durable design for fibrous proteins. Larger bonding surfaces are available for interaction of subunits than would be available in a comparable structure made of globular subunits. In the minimum energy configuration¹⁶ for such an assembly, there are likely to be regular contacts along the length of neighbouring subunits, resulting in similar bonds at different radii. These bonds will be related by symmetry elements that operate not just in the surface lattice of the helix, but in three dimensions.

For the conformation derived experimentally for class II coat protein subunits, the α -helix axis roughly follows a segment of a conchospiral, a space curve with many interesting symmetry properties^{17,18}. The conchospiral is given by the equations

$$\begin{aligned} r &= a \exp(\phi \cot \alpha \sin \gamma) \\ z &= c \exp(\phi \cot \alpha \sin \gamma) \\ \tan \gamma &= a/c, \end{aligned}$$

where r, ϕ, z are cylindrical polar coordinates, α is the constant angle that the tangent to the curve makes with the z axis, and γ is the half-angle of the cone on which the conchospiral lies. This curve is the most symmetrical space curve aside from the circular helix. The curvature and torsion of the curve change continuously in a regular way as one progresses along the curve, giving regular internal symmetry. The segments of conchospiral in the filamentous virus helix are located so that each segment is roughly centred along its length between its nearest neighbours. There are two main kinds of intermolecular contacts: from any protein molecule to the proteins originating five and nine units, respectively, down the ~ 15 Å virus helix (Fig. 5). In the class II structure these contacts are sufficiently similar so that each protein in the helix has essentially equivalent environments in both directions, although a faint meridional reflection on the ~ 15 Å layer line indicates a slight perturbation repeating periodically about once per turn of the ~ 15 Å virus helix. The corresponding meridional reflection on class I patterns, and by implication the associated perturbation, is much stronger⁴. Contacts between the class I α helices that correspond to the 0 to -5 class II contacts in Fig. 5 are regular, but contacts corresponding to 0 to -9 are irregular, with a perturbation that repeats about every five units. This perturbed configuration presumably optimises local contacts and is therefore more stable than any unperturbed configuration that could be formed by the class I subunits.

Three principles for the design of linear assemblies of proteins are suggested by the detailed studies of filamentous viruses. (1) Linear assemblies will often be composed of axially elongated overlapping subunits. (2) Interdigitation of elongated subunits in neighbouring turns of the helical array will be facilitated if there are (roughly) an odd number of units in two turns of the helix. (3) Contacts between interdigitating neighbours will often be improved by a perturbation away from the ideal helical positions, repeating once every turn of the helix, and giving rise to a set of meridional reflections at orders of a periodicity that corresponds to the pitch of the helix rather than to the subunit spacing. Overlapping arrangements of elongated subunits have been proposed for myosin filaments in muscle¹⁹⁻²¹. Sharp meridional reflections have been observed on diffraction patterns of many fibrous proteins¹³, and in some cases have been interpreted in terms of perturbation. Some linear assemblies,

Fig. 4 Axial section of the class II model. A 14 Å slab through one virion, equivalent to four helix asymmetric units, is shown for convenience in visualising the packing of neighbours. *a*, Ball-and-stick representation of the α -carbon atoms, projected on to a plane normal to the axis of the virion. Numbers indicate residues. Several segments of different α helices overlap, but can be distinguished by discontinuities in the sequence of numbers. The basic residues (20, 44 and 45) and acidic residues (4, 14 and 18) are indicated by + and -, respectively. The box measures 30 Å on a side. *b*, Electron density in a corresponding slab, calculated⁶ using³⁶ the observed amplitudes and the phases of the protein model shown in Fig. 3. For the equator, phases were taken from Fig. 7*b* of ref. 15, and amplitudes from continuous transform of a non-crystalline Pf1 fibre at 100% relative humidity, measured and corrected for residual crystalline reflections as described in ref. 15. Crosses indicate the positions of axes of α helices in the model. Zero contours are dashed and may enclose negative density. Although DNA was not included in the phasing, it is expected that phases calculated on the basis of the protein model alone will be approximately correct, and may reveal structure not included in the model, such as possible phosphate peaks in the central DNA region.

Fig. 5 Model of a 154 Å slab of the protein coat of the virus. The long axis of the virion is vertical. The protein subunits are represented by bent rod following the path from one α carbon to the next. Three neighbouring α helices are picked out by lengths of tubing: they are shown in the same view as Fig. 3 of ref. 14. The right-most α helix originates five units down the ~ 15 Å helix with respect to the central α helix, and the left-most α helix originates nine units down. Note the gentle curve of the α helices, and the interdigitation of neighbouring helices. DNA would occupy the central cylindrical cavity in the protein shell. The outer diameter of the lucite support rod is 6 Å in the model.

such as microtubules or bacterial flagella that have been assumed to be composed of globular subunits²²⁻²⁴ should perhaps be re-examined in the light of these principles.

Assembly

With the molecular structure of the virion in hand, we can discuss specific hypotheses about viral assembly. We assume the model of assembly illustrated in Fig. 1, and restrict ourselves to the steady-stage of assembly, after the forward end of the virion has passed across the membrane. The viral coat protein is a single rod of α helix with a hydrophobic central portion and hydrophilic ends. The protein could be excreted directly into the lipid bilayer²⁵ during synthesis²⁶, with its N-terminal end outwards and its long axis normal to the plane of the bilayer². The DNA, stripped of the gene 5 protein would, form a condensation centre for the coat protein previously stored in the bilayer. As the protein assembled on to the DNA, its hydrophobic areas would become masked, so that the protein would become less soluble in lipid than in water and therefore

would leave the lipid for the water, taking associated DNA with it. The process would be akin to crystal growth where the growing point of the crystal is fixed in space so that the crystal must move away from the growing point. The sense of the process (the virion moves out of rather than into the bacterium) would depend on the details of the configurational change in the coat protein upon assembly. A similar process in reverse could drive the dissolution of protein off the virion into the lipid bilayer²⁷ and advance the DNA into the bacterium during infection. This model—that assembly of hydrophobic proteins within a lipid bilayer causes changes in the properties of the completed assembly so that it becomes more soluble than the monomer in an aqueous phase and thus moves out of the bilayer—could apply in general to transport of oligomeric or polymeric proteins through membranes.

This investigation was supported by a grant from the National Institutes of Health.

Measurement of circular polarisation in the Crab Nebula at 1,415 MHz

RECENTLY Rees and Gunn¹ suggested that the 30-Hz wave power probably emerging from the Crab Nebula Pulsar NP0532 does not propagate further than a small region around the pulsar with a radius of about 10% of the nebular radius. Beyond this, in the main body of the nebula, the magnetic field is built up in toroidal form to equipartition strength so that the continuum emission from the bulk of the nebula is entirely synchrotron radiation. The axis of this toroid is aligned with the rotational axis of the pulsar which is assumed to be lying in the plane of the sky along the major axis of the nebula (NW/SE). A test of this proposal is the measurement of a characteristic sign change in the distribution of Faraday rotation or circular polarisation over the nebula. If the nebula is divided into quadrants along its major and minor axes, then adjacent quadrants should have the opposite sign and opposite quadrants the same sign. Since any measured Faraday rotation does not necessarily arise within the body of the nebula, the critical test becomes a detection of the characteristic sign distribution in the small amount of circular polarisation ($\sim 0.1\%$) expected at radio frequencies from ordinary synchrotron radiation². The theoretical frequency dependence of $\nu^{-1/2}$ for the fraction of circular polarisation would then explain the null result of Landstreet and Angel³ (see also ref. 4) at optical frequencies. Here I report a measurement of the distribution of circular polarisation (Stokes parameter V) in the Crab Nebula at 1,415 MHz obtained during a series of high accuracy full polarisation measurements with the Westerbork Synthesis Radio Telescope in November 1971.

A brief description of the normal method of polarisation measurement with the Synthesis Telescope can be found in ref. 5. In our case, this was modified by having, in each of the 20 simultaneous interferometers, the crossed dipoles in both telescopes parallel rather than at the usual 45 degrees to each other. The corrections for instrumental polarisation of the order of 1% of the total intensity were determined by observing 3C48 for 2×12 h and assuming that it was totally unpolarised at 1,415 MHz. It has been shown by Conway *et al.*⁶ ($V = +0.015 \pm 0.010\%$ at 1,415 MHz) and by Berge and Seielstad⁷ ($V = -0.024 \pm 0.024\%$ at 1,420 MHz) that this assumption is accurate for the V component with which I am concerned here. The final accuracy of the measurement of the distribution of circular polarisation in the Crab Nebula was then approximately 0.02% of the total intensity.

The great radio flux of the nebula overloaded all interferometer baselines shorter than 300 M and these had to be eliminated from the observation. Thus, the circular polarisation map is mainly sensitive to the smaller scale features in the source and not to the broader extended structure.

The resulting map of the distribution of circular polarisation in the Crab Nebula is presented in Fig. 1. The vertical and horizontal scales refer to the position of the pulsar (the cross). The r.m.s. noise error in the map is approximately one contour. Because of the missing short interferometer spacings, the area of the synthesised beam is not well defined and a conversion of the brightness contours to units of temperature will not be attempted. Even though V can assume both positive and

negative values, the negative feature to the west of the pulsar cannot, in this case, be distinguished from the effect of the missing short spacings. Also, since its magnitude is only about twice the r.m.s. noise error in the map, I do not consider it to be a real negative component of circular polarisation. Similarly, although feature A on the map cannot be generated by the effect of missing short spacings, it is only twice the r.m.s. noise error and thus of marginal significance.

For comparison with the distribution of total intensity, Fig. 2 shows the total intensity map from Duin and van der Laan⁸ obtained with the Westerbork Synthesis Telescope in a special detuned observing configuration which avoided the saturation problems discussed above. The frequency of observation and the resolution are the same as in Fig. 1 and a direct comparison of the maps can be made. From this it is possible to compute the circular polarisation for the four lettered areas as 0.04% (A), 0.05% (B), 0.06% (C) and 0.05% (D). These values can only be rough estimates due to the possibility of an undetected larger scale background in the source. They are, however, consistent with the amount of circular polarisation

Fig. 1 Contours of the circular polarisation (Stokes parameter V) for the Crab Nebula at 1,415 MHz. The contour interval is 2.5 mJy per synthesised beam area. Positive contours are solid and represent right-hand circular polarisation (IRE definition). Negative contours are dashed and no zero contour is plotted. The heavy outside contour (taken from Duin and van der Laan⁸) is where the total intensity has 10% of its peak value. The cross marks the position of NP0532 (α (1950.0) = 05 h 31 min 31.46 s; δ (1950.0) = $21^\circ 58' 54''.8$). The half-power synthesised beam width is shown in the lower left corner.

Fig 2 Contours of the total intensity (Stokes parameter I) at 1,415 MHz from Duin and van der Laan⁸. The contour interval is 2 Jy per synthesised beam area and the peak brightness is 25 Jy per synthesised beam area. The zero contour is plotted dashed. The cross marks the position of NP0532. The resolution and horizontal and vertical scales are the same as in Fig 1.

expected from normal synchrotron radiation in a static magnetic field of 10^{-3} to 10^{-4} gauss.

The major feature of Fig 1 is that whenever circular polarisation is detected, its sign is positive, indicating an average line-of-sight component of the magnetic field directed towards us. There is no indication of the sign reversal between adjacent quadrants expected from a toroidal structure.

The simplest magnetic field structure consistent with the present measurements is that of a relatively uniform field of 10^{-3} to 10^{-4} gauss directed with its line-of-sight component towards us. This form and strength is then quite similar to that suggested by Weiler and Seielstad⁹ from synthesis measurements of the linear polarisation and Faraday rotation at radio wavelengths. An effective mechanism for maintaining and amplifying such a field during the lifetime of the nebula is, however, still needed.

An independent confirmation of the circular polarisation in the Crab Nebula would be extremely useful. Thus, it should be noted that the presence of only positive values of V in the synthesis map implies that the integrated radiation should have a detectable amount of circular polarisation at radio frequencies. This could be of the order of 0.05–0.1% at 1,415 MHz and theoretically more at lower frequencies. There is only one previous measurement of the fraction of circular polarisation in the integrated radiation of the Crab Nebula at radio wavelengths which exceeds 0.1% in accuracy. Seielstad and Weiler⁷ found $+0.13 \pm 0.09\%$ circular polarisation at 1,418 MHz from measurements with the Owens Valley interferometer. Although this is insufficiently larger than the errors to be trusted, it is interesting that it agrees in sign with the present measurements.

We thank the staff of the Westerbork Observatory and the members of the Reduction Group at the University of Leiden for assistance, and Dr E. Raimond for advice and suggestions.

The analysis was carried out with the interactive software described by Ekers *et al.*¹¹ at Computing Centre of the University of Groningen. The Westerbork Radio Observatory is operated by the Netherlands Foundation for Radio Astronomy with the financial support of the Netherlands Organisation for the Advancement of Pure Research (ZWO).

Nucleosynthesis and matter–antimatter cosmologies

If light elements are of cosmological origin, then a given cosmological model should be able to reproduce the observed abundances¹. Symmetric matter–antimatter cosmologies^{2–4} do not stand up to this test too well, and encounter problems whose basis is the annihilation process itself.

Steigman⁵ has emphasised that there is an important loss of neutrons at temperatures of the order of 1 MeV. (The matter–antimatter separation is assumed⁴ to have taken place at temperatures of the order of 350 MeV.)

Protons are essentially 'frozen' within a matter region by electrostatic interactions, and do not diffuse towards the matter–antimatter interface, this, however, is not true of neutrons, which are affected only by the interactions of their magnetic moment with that of the electrons (for which the cross section is very low) and by elastic collisions with protons. When the temperature has dropped below 1 MeV, weak interactions can no longer maintain an equilibrium between the protons and neutrons, and the neutron abundance in a region within a diffusion length of the interface ($\sim \sqrt{Dt}$), where D is the neutron diffusion coefficient and t the time, will drop as a consequence of the annihilation which occurs there.

It follows that the neutron–proton ratio, on which nucleosynthesis depends, is essentially a function of the ratio of the neutron diffusion length to the mean size of a matter region. Now, according to Omnès⁶, the size of a matter region turns out to be of the order of a neutron diffusion length: the neutrons must therefore all escape and be annihilated. Under these conditions primordial nucleosynthesis cannot take place.

Nevertheless, this estimate for the typical size of a matter region is not necessarily the only possible one, since there is some considerable uncertainty about the physical processes which occur at temperatures above 1 MeV, one might therefore try to fix empirically the 'size of the emulsion' (the somewhat misleading term often used to denote the size of a matter or antimatter region) by requiring that the symmetric model give the observed abundances.

To do this, we have to modify the usual evolution equation for the neutrons⁶, since the annihilation follows diffusion. If we suppose that all neutrons which reach the interface are annihilated, the evolution equation can be written as

$$dn/dt = \lambda p - \hat{\lambda} n - (Dt/4\pi)^{1/2} n/Lt \quad (1)$$

using the notations of ref. 6, D being the neutron diffusion coefficient and L the emulsion size (L is a function of temperature). The proton evolution equation is written in the usual way, since the diffusion is negligible

$$dp/dt = \hat{\lambda} n - \lambda p \quad (2)$$

If we suppose that L varies with temperature as $L = L_1 T^{-1}_{\text{MeV}}$ cm, we can integrate equations (1) and (2) to obtain a lower limit for the emulsion size at $T=1$ MeV that is, $L_1 \gtrsim 3 \times 10^6$ cm. The calculations have been done using various other equations for L (simple power laws, a sequence of different power laws joined piecewise), and it turns out that the smallest emulsion size is obtained by taking account only of expansion. This is the smallest emulsion size for which annihilation does not affect the relative neutron abundance: therefore, at the end of nucleosynthesis ($T \sim 0.1$ MeV), the light elements will have their usual¹ abundances.

At this epoch, the Universe is a matter-antimatter emulsion consisting for the most part of protons and helium nuclei together with the corresponding antielements. Although nucleosynthesis has finished, the annihilation processes themselves continue: an antiproton reaching the interface can annihilate against a proton or one of the nucleons within a helium nucleus, producing in the latter case a deuteron together with a number of neutrons. The deuterons produced in this kind of reaction will have a large kinetic energy, will leave the annihilation zone and, being charged, will be slowed down rapidly in the matter region. We shall call this 'direct deuterium'. It can be shown that all the neutrons will also be thermalised by elastic collisions with protons and helium nuclei, note, however, that this process is somewhat slower. As soon as they are sufficiently slow, they are captured by the protons to create more deuterium—this will be referred to as 'indirect deuterium'. The capture cross section rises very rapidly at low energies.

The annihilation rate per unit surface depends only on the nucleon flux at the interface, and so is independent of the emulsion size. Therefore, the annihilation rate per unit volume is inversely proportional to L : the smaller L , the larger the number of annihilations $\bar{p}-\alpha$ and the larger the amount of deuterium produced. Now, we must not at this stage produce too much deuterium (subsequent stellar destruction cannot lower the amount by an order of magnitude)—deuterium formation after the end of nucleosynthesis introduces therefore a new constraint on the emulsion size.

To calculate the amount of deuterium produced by this process, we have to know the branching ratios of the reactions $\bar{p}-\alpha \rightarrow d + \text{anything}$ and $\bar{p}-\alpha \rightarrow n + \text{anything}$. Since very little experimental and theoretical information is available, the following very rough model has been used. We suppose that the low energy ($E_{\text{kin}} \leq 1$ MeV) antiproton annihilates against the first nucleon which it meets in the ${}^4\text{He}$ nucleus, and produces an average of 5–6 pions. Experiment⁷⁻¹⁰ suggests that, on average, only one of these pions interacts with the remaining nucleons, which are still sufficiently close together to be treated as a ${}^3\text{He}$ or ${}^3\text{H}$ nucleus. The reaction $\pi-{}^3\text{He}$ (ref. 11) has been studied experimentally for pions at rest, and so the number of deuterons produced per interaction (~ 0.25) is probably overestimated and the number of neutrons (~ 1.75) underestimated. There could be ~ 7 times as much indirect deuterium produced as direct if each neutron were captured. Detailed calculations¹², which take into account the path lengths of the various different particles, show that to a first approximation we may in fact neglect the direct deuterium.

An appreciable quantity of deuterium will be produced only if the capture process $p+n \rightarrow d+\gamma$ be more important than the photodissociation $d+\gamma \rightarrow p+n$, that is if the temperature be below 0.07 MeV. We shall denote the time at which this temperature is reached by t_i . This production stops when the temperature is so low that the neutron decay has become more important than capture: this occurs at the time t_f . The deuterium abundance is therefore calculated for the interval $t_i - t_f$.

$$d/p = \int_{t_i}^{t_f} (\nu L^2 B) \times \frac{1}{2} \frac{75}{dt/pL^3} dt$$

where d and p are the number densities of deuterium and protons respectively, ν is the $\bar{p}-p$ annihilation rate (it can easily be shown that $B \sim \alpha < \sigma v >_{\bar{p}p} / < \sigma v >_{pp}$, where α is the number density of helium, the other quantities having their usual meaning¹³), $L = L_1 T^{-1}_{\text{MeV}}$ is the emulsion size. Note that we have introduced a factor $\frac{1}{2}$ because, on average, one half of the products of a $\bar{p}-\alpha$ annihilation pass into a matter region, and one half into an antimatter region.

In order that this process does not produce more deuterium than is observed^{1,14} $d/p \lesssim 10^{-5}$. The emulsion size at a temperature of 1 MeV is therefore given by $L_1 \gtrsim 1.5 \times 10^8 (\Omega h'^2)^{1/3}$ cm, where Ω is the density parameter and $h' = H_0/50$ (H_0 is the Hubble constant in $\text{km s}^{-1} \text{Mpc}^{-1}$).

During the radiative era, the nucleon number density rises by a factor of $\sim 10^3$ as a consequence of annihilation, any subsequent annihilation will therefore affect the element abundances very little.

So the amount of helium and deuterium produced as a consequence of nucleosynthesis can be made to agree with observed abundances only if the emulsion size at 1 MeV exceeds the neutron diffusion length by a factor of about 10^3 (at this epoch, $\sqrt{Dt} \sim 10^4$ cm).

Nevertheless, it would at this stage be unwise to discuss the future of symmetric cosmologies. Our present state of knowledge does not allow us to calculate the emulsion size in any definitive way.

We thank E. Schatzman for guidance and S. Caser, J. L. Puget and R. Omnes for comments.

Of fundamental electrodynamics and astrophysics

MAXWELL's equations are well established for phenomena on laboratory and terrestrial scales, but there are other electrodynamic theories, as yet indistinguishable on such scales from Maxwell's theory, that have significantly different consequences for phenomena on an astronomical scale. For example, extensive magnetic fields are possible in the Universe¹ because of the general absence of magnetic monopoles. Parker¹ considered the abundance of magnetic monopoles that would neutralise or dissipate the magnetic fields of the Earth, Sun and the Galaxy, and deduced for the number density of free magnetic monopoles upper limits that are more stringent than those deduced from laboratory and terrestrial data.

Another example of electromagnetic equations that might be relevant to the description of astrophysical phenomena are the Proca equations, which may be interpreted in terms of a non-zero photon rest mass. A consequence of the Proca equations is that static electric and magnetic fields in free space decay exponentially with distance from the source. For phenomena on scales comparable with or exceeding the characteristic length for decay, the description provided by the Proca equations departs from that provided by the Maxwell equations. In static space-time the Proca equations, like the Maxwell equations, predict that electromagnetic waves propagate with fixed frequency, contrary to what has been claimed^{2,3}, the Proca equations do not form a basis for the 'tired-light' interpretation of the cosmological redshift.

Laboratory and terrestrial experiments have determined⁴ that the photon rest mass, m , is less than about 3×10^{-48} g, astrophysical considerations have led to an improvement by about four and a half orders of magnitude⁵. Here, we obtain an upper limit on m from consideration of the Proca equations and the mass of the Galaxy.

The Proca equations show that $(\mathbf{E}^2 + \mathbf{H}^2 + \mu^2 \phi^2 + \mu^2 \mathbf{A}^2)/8\pi$ can be interpreted as the energy density of the electromagnetic field⁴, \mathbf{E} and \mathbf{H} are the electric and magnetic fields, ϕ and \mathbf{A} are the scalar and vector potentials and $\mu^{-1} = h/2\pi mc$, where h is Planck's constant and c is the relativistic limiting speed. If ρ denotes an upper limit on the mean mass density of matter and energy in all forms that could exist in a region of space in which a magnetic field is observed, the $\mu^2 \mathbf{A}^2/8\pi c^2 \lesssim \rho$. The relationship $\mathbf{H} = \Delta \times \mathbf{A}$ shows that $|\mathbf{A}| \sim |\mathbf{H}| L$ where, for an approximately uniform magnetic field, L is of the order of the smallest dimension. Thus, the above inequality leads to

$$\mu^2 \lesssim 8\pi \rho c^2 / \mathbf{H}^2 L^2 \quad (1)$$

The Galactic magnetic field in the vicinity of the Sun has been observed⁶ to have a strength of about 2×10^{-6} gauss and is approximately uniform over a distance of at least 300 pc, so that in the Galactic disk L may be estimated as greater than about 10^{20} cm. The masses of galaxies may be estimated from their rates of differential rotation and from the orbital velocities of binary systems, it has been deduced⁷ that for many galaxies the mass exceeds the total mass of known stars by an order of magnitude. The mass of the Galaxy is often quoted⁸ at about $10^{11} M_\odot$ so that $10^{12} M_\odot$ is a conservative upper limit on the mass of the Galactic disk. Thus, using the dimensions given by Allen⁸, $\rho \lesssim 10^{-21}$ g cm⁻³ for the Galactic disk. Assuming that the interstellar magnetic field in the vicinity of the Sun is typical of magnetic fields of the Galactic disk, equation (1), with $|\mathbf{H}| \sim 2 \times 10^{-6}$ gauss, $L \gtrsim 10^{20}$ cm and $\rho \lesssim 10^{-21}$ g cm⁻³, leads to $\mu \lesssim 3 \times 10^{-14}$ cm⁻¹, corresponding to $m \lesssim 10^{-51}$ g. This limit is not far from the best available upper limit⁵ of 10^{-55} g.

In interstellar space the energy densities resulting from radiation from stars, turbulent gas motions, universal background radiation and cosmic rays are all of a similar order of magnitude to the Maxwellian energy density $\mathbf{H}^2/8\pi$, associated with the

magnetic field⁸, if $m \sim 10^{-52}$ g, then the energy density $\mu^2 \mathbf{A}^2/8\pi$ exceeds these energy densities by 11 or more orders of magnitude. It may well be that the upper limit of 10^{-52} g could be improved by consideration of the possible sources of the energy density, $\mu^2 \mathbf{A}^2/8\pi$, associated with large scale magnetic fields and of instabilities that may result from this energy density. Conversely, it is worth bearing in mind that large energy densities associated with large scale magnetic fields and a non-zero photon rest mass could be significant in some astrophysical processes.

Oblique rotators in binary systems

RADIO pulsar PSR1913+16, which has a period of about 59 ms, has been identified as a member of a binary system¹. The X-ray 'oscillars' HerX-1 and CenX-3, which are also members of binary systems, are not radio pulsars (I use the word 'oscillars' to distinguish these objects from pulsars, which maintain their periodicity much more accurately). These facts, together with the 34-d periodicity^{2,3} of HerX-1 and the lack of this periodicity in CenX-3, can be explained by using the rotating neutron star hypothesis for the compact object in all of these systems. As is common in pulsar theories, I assume that rotating neutron stars are oblique rotators, that they have magnetic fields and that the magnetic axes are not along the axes of rotation.

An oblique rotator, with a magnetic field, B , a period of rotation, P , and radius, R , gives out low frequency radiation with energy⁴

$$E \simeq 10^{-28} B^2 R^6 / P^4 \text{ erg s}^{-1}$$

Using $B \sim 10^{12}$ gauss, $R \sim 10^6$ cm and a period, P , of 59 ms, PSR1913+16 gives out about 5×10^{37} erg s⁻¹ of low frequency radiation. This is quite close to the Eddington limit and can equal it with only a slight variation of B or R . Radiation of this intensity opens the equipotential lines near the first Lagrangian point⁵, and accretion of matter from the binary companion is thus prevented. The radio emission, which is attributed to a polar phenomenon⁶ can, therefore, occur without interference from accreting matter. The lack of accretion prevents PSR1913+16 from becoming an X-ray oscillator like HerX-1 or CenX-3. On the other hand, PSR1913+16 could be an X-ray pulsar like NP0532, but with considerably smaller flux.

HerX-1 has an X-ray periodicity of 1.24 s and if this is attributable to the rotation period of the neutron star, the low frequency radiation emitted is about 5×10^{31} ergs s⁻¹. CenX-3 has a period of 4.8 s and gives out about 2×10^{29} erg s⁻¹.

These values for energy emission are considerably smaller than the Eddington limit and so matter could accrete on to the neutron star. If the radio emission process is to continue, that matter must absorb the radio radiation by the free-free process. This can be verified by considering the rate of accretion implied by the X-ray emission of HerX-1 and CenX-3. Thus, it can be seen why HerX-1 and CenX-3 are not radio pulsars.

The low frequency radiation emitted by HerX-1, though not large enough to prevent mass accretion, still regulates it in an interesting manner. Suppose that the density of matter at a distance r from a neutron star of mass, m , ($\sim 1M_{\odot}$) is ρ . Then, equating the radiation pressure and the gravitational force

$$GM\rho/r^2 = 5 \times 10^{31}/4\pi r^2 c$$

where G is the gravitational constant and c is the velocity of light. This gives $\rho \simeq 10^{-6} \text{ g cm}^{-3}$, and thus in the case of HerX-1 unless the density is higher than about $10^{-6} \text{ g cm}^{-3}$, accretion cannot occur. The matter accreting from the binary companion piles up at the light cylinder and when the density exceeds the calculated value accretion starts and continues until the density again reaches the critical value. Thus, it could be taking 22 d to accrete enough matter to reach the required density, and 12 d for all the released matter to spiral into the neutron stars, during which time X-ray emission occurs. That would also allow the emission of X rays during the 22-d quiescent period, as has been observed⁷. For when the companion star ejects matter as, for example, in a flare, the density in the reservoir may exceed the required value in less time than the average accretion time and so X-ray emission could occur.

In the case of CenX-3, the emission of low frequency radiation is much smaller than in HerX-1, and only low densities of matter are needed to overcome the radiation pressure. Therefore, accretion can occur all the time.

Another interesting effect on the oblique rotator in a binary system is the oscillation of the magnetosphere of the neutron star. This occurs because of the gravitational force of the companion star on the matter in the magnetosphere, somewhat similar to the tidal effect on Earth. This makes the lines of force, which are assumed to be frozen in, vibrate as the neutron star rotates. By calculation I found that in the case of HerX-1 the fluctuation of the field intensity is 100% at around a few times 10^9 cm . The effect of this fluctuation is to accelerate particles. But the energy involved is only about 10^{32} – $10^{33} \text{ erg s}^{-1}$. A detailed account will be presented elsewhere.

Note added in proof Margon *et al.*⁸ observed PSR1913+16 for an hour using the Copernicus satellite, for X-ray emission in the region 1–3 Å. They did not find any X-ray flux and give an upper limit to $10^{-10} \text{ erg cm}^{-2} \text{ s}^{-1}$. The non-observation of X-ray flux from PSR1913+16 is consistent with the model suggested above, since the low frequency radiation prevents accretion.

Polarisation of atmospheric bremsstrahlung

THE terrestrial atmosphere is bombarded continuously by energetic charged particles of extraterrestrial origin. When a charged particle penetrates deep into the atmosphere, either its direction changes or its speed varies with respect to the local phase velocity of electromagnetic waves. These changes, caused by the dense atmosphere at altitudes of about 90–100 km, generate bremsstrahlung X rays. The flux of atmospheric bremsstrahlung X rays has been measured using balloons^{1–3}, rockets and satellites^{4,5}. Measurement of the atmospheric X-ray flux has become routine in the study of electron flux precipitation into the lower ionosphere^{6,7}. The degree of polarisation of emitted radiation changes rather drastically with the changing energy of precipitating electrons and with the height of precipitation. But no effort has yet been made to measure the polarisation of atmospheric bremsstrahlung. We here show the potential importance of bremsstrahlung X-ray polarisation and its probable role in atmospheric diagnostics.

In the auroral zone electron penetration is almost vertically downwards. Electrons penetrating the dense atmosphere give rise to linearly polarised bremsstrahlung X-ray photons. The degree of linear polarisation is a function of the kinetic energy of scattering electrons, the energy of the emitted photons, the angle of photon emission with respect to the direction of the incident electron, and the atomic number density of atmospheric gas. The classical and quantum mechanical theories of linear polarisation of bremsstrahlung X rays have been fully developed. The success of a diagnostic technique is based primarily on the compatibility between experimental measurements and theoretical computations. But the theoretical computation of the degree of linear polarisation using rigorous quantum mechanical theory, and the detailed nature of target structure have posed a serious problem. This has inhibited the use of the degree of polarisation as a diagnostic measure. Kirkpatrick and Wiedmann⁸ have developed an approximate computational procedure for obtaining the degree of polarisation as a function of the projectile and target parameters. Using that procedure we have computed the height profile of the degree of polarisation of bremsstrahlung X rays in the terrestrial atmosphere and have shown its variation with related parameters.

Bremsstrahlung X rays received at a point in the z - x plane (z being vertical), at an angle θ relative to the incident electron direction can be resolved into two linearly polarised intensity components, I_{\perp} and I_{\parallel} . The radiated X ray is assumed to be linearly polarised in the direction of the emitting equivalent

Fig. 1 Variation of the degree of polarisation with height of 20 and 40 keV electrons (dashed and solid lines, respectively) for different angles of photon emission.

dipole. Therefore, I_{\perp} will have only a y component whereas I_{\parallel} will have x and z components. Thus

$$\begin{aligned} I_{\perp} &= I_y, \\ I_{\parallel} &= I_x \sin^2\theta + I_z \sin^2(90^\circ - \theta) \end{aligned} \quad (1)$$

For an unpolarised electron beam there exists an axial symmetry so that

$$\begin{aligned} I_y &= I_z, \\ \text{and } I_{\parallel} &= I_x \sin^2\theta + I_y \cos^2\theta \end{aligned} \quad (2)$$

From equations (1) and (2) the degree of linear polarisation can be defined as

$$P(\theta) = \frac{(1 - I_y/I_x)}{[(I_y/I_x)(2\csc^2\theta - 1) + 1]} \quad (3)$$

By this definition the degree of polarisation, $P(\theta)$, ranges from +1 (complete polarisation perpendicular to the electron-photon plane) to -1 (complete polarisation parallel to that plane).

In view of the difficulties involved in the computation of I_x and I_y using rigorous quantum mechanical theory we have resorted to an approximate method following Kirkpatrick and Wiedmann⁸

$$I_x = 10^{-50} (Z^2/V) [0.252 + a((v/v_0) - 0.135) + b((v/v_0) - 0.135)^2] \quad (4)$$

and

$$I_y = I_z = 10^{-50} (Z^2/V) [-j + k/(v/v_0 + h)] \quad (5)$$

where v_0 and v are the photon frequencies corresponding to the initial and final energies of the scattering electrons, V is the velocity of electrons in e.s.u. and Z is the atomic number of the scatterers. The constants a , b , h and k are empirical constants defined by Kirkpatrick and Wiedmann⁸

The height profile of V/Z^2 and v/v_0 have been obtained from detailed computation of the energy degradation of charged particles into the ionosphere^{9,10}. I_x and I_y are functions of the height profiles, V/Z^2 and v/v_0 which give rise to the height profile of $P(\theta)$ (Fig. 1). It is obvious from Fig. 1 that measurement of the degree of polarisation, $P(\theta)$, at a particular height is very sensitive to changes in the energy of incident electrons and to the direction of the emitted photons. The height of the transition of the plane of polarisation from + to - changes with the changing incident energy of the electrons. The height of the transition is, however, independent of the angle of bremsstrahlung photon emission. This variation with height suggests that simultaneous measurements at different heights could allow the prediction of degradation of electron energy and changes in electron flux. The lack of a high efficiency, high resolution X-ray spectrometer has been the main reason for the paucity of experimental measurements of the polarisation of bremsstrahlung radiation produced by low energy electrons. The advent of the Ge(Li) detector has solved this problem and it seems quite feasible that the measurement of polarisation could be used as a diagnostic probe for studying precipitating electron energy and flux.

Landau damping and cyclotron resonance in uniform magnetoplasma

The formation of a ledge in the electron distribution functions during Landau damping produces steep gradients at the boundaries of the disturbed region of the distribution function. This makes the pitch angle distribution sufficiently anisotropic to amplify a gyroresonant whistler mode perturbation at the appropriate frequencies.

The system under consideration consists of a homogeneous, collisionless hot plasma in a uniform magnetic field B_0 , a spectrum of electron plasma waves with their propagation vectors k antiparallel to B_0 , and a wide band whistler mode perturbation with k parallel to B_0 . For simplicity, the particle distribution f is taken to be initially independent of pitch angle $\alpha = \tan^{-1}(v_{\perp}/v_{\parallel})$ where v is the particle velocity and the subscripts \parallel and \perp refer to the vector components along and perpendicular to B_0 .

The electron plasma waves would be Landau damped with a growth rate¹ γ_L varying as $\partial f / \partial v_{\parallel}$ at $v_{\parallel} = v_{res}$, where $v_{res} = \omega_p/k$ is the Landau resonant velocity, ω_p being the electron plasma frequency. Simultaneously, the electron distribution would evolve quasilinearly in accordance with the equation¹

$$\partial f / \partial t = (\partial / \partial v_{\parallel}) [\{ (4\pi e^2 / m^2 v_{\parallel}) (E_k^2 / 8\pi) \} (\partial f / \partial v_{\parallel})] \quad (1)$$

where e and m are the electron charge and mass respectively and $E_k^2 / 8\pi$ is the energy density of the wave.

The growth rate² γ_c for the whistler mode perturbation, which results from cyclotron resonance with electrons is proportional to $(A(V_R) - B)$ where

$$A(V_R) \propto \left[\int_0^{\infty} v_{\perp} dv_{\perp} \{ v_{\parallel} (\partial f / \partial v_{\perp}) - v_{\perp} (\partial f / \partial v_{\parallel}) \} v_{\perp} / v_{\parallel} \right]_{v_{\parallel} = V_R} \quad (2)$$

and $B = \omega / (\Omega - \omega)$ with $V_R = (\omega - \Omega) / k$ and $\Omega = eB_0 / mc$

Fig. 1 Upper part f against v_{\parallel} , k is negative. The ledge (a) forms with negative values of v_{\parallel} (b). Disturbed region. Lower part $\partial f / \partial v_{\parallel}$, at different points of the ledge, against v_{\parallel} . The steep rise in f at the boundaries of b gives the peaks in $|\partial f / \partial v_{\parallel}|$.

Fig 2 Behaviour of growing waves with time. Upper part frequency growing fastest at time t , against t . The curve has two branches, one above and one below the central frequency. Lower part maximum growth rate at time t , against t .

The cyclotron growth of the perturbation, in turn, affects the pitch angle distribution of the particles, which then evolves in accordance with the equation² (for $\omega \ll \Omega$)

$$\partial f(v, \alpha, t) / \partial t = (\pi e^2 / m^2 \sin^2 \alpha) (\partial / \partial \alpha) \{ (\sin \alpha B_z^2 / |v \cos \alpha|) (\partial f / \partial \alpha) \} \quad (3)$$

where $B_z^2 / 8\pi$ is the magnetic energy density of the whistler mode wave. Since $\partial f / \partial \alpha$ and $\partial f / \partial v_{||}$ are not independent, the resultant effect of the electron plasma and whistler mode waves on the electron distribution in the range where V_R and v_{res} overlap can be obtained by solving equations (1) and (3) simultaneously. Exact analytical solution of these equations is, however, very difficult and therefore, it would be worthwhile to look qualitatively into the behaviour of these equations.

For simplicity, only the initial stage of the growth of the whistler mode perturbation is considered, when its amplitude is too small to affect the background distribution significantly. For $\omega \ll \Omega$, $\gamma_c \propto A(V_R)$ and V_R is always negative. For a monotonically decreasing f with increasing $|v_{||}|$ and v_{\perp} , equation (2) gives

$$A(V_R) \propto \left[\int_0^\infty v_{\perp}^2 \partial v_{\perp} \{ |v_{\perp}| / |v_{||}| \} \{ \partial f / \partial v_{||} - |\partial f / \partial v_{\perp}| \} \right]_{v_{||} = V_R} \quad (4)$$

For an initially isotropic distribution $A(V_R) = \gamma_c = 0$ at $t = 0$. The quasilinear diffusion process caused by electron plasma waves leads to the formation of a ledge in f over the range of the resonant velocities. During this process $|\partial f / \partial v_{||}|$ diminishes at the centre but develops peaks on either side of the ledge (Fig 1), which grow in height and drift in position towards the boundaries of the disturbed region (Fig 2). As $\partial f / \partial v_{\perp}$ does not change during Landau resonance, the changes

Fig 3 a, f against $v_{||}$ at $t = 0$, b, largest $v_{||}$ for Landau resonance, c and d, the resulting disturbed and undisturbed regions, respectively, e, the ledge formed over c after quasilinear relaxation, g unchanged f over d. The steep gradient, $\partial f / \partial v_{||}$, that develops near $v_{||} = c\Omega/2\omega_p$ would increase the pitch angle anisotropy and lead to whistler growth.

in $A(V_R)$ and γ_c (at corresponding frequencies) would follow those in $|\partial f / \partial v_{||}|$.

If ω is not much less than Ω , then γ_c will not become positive unless $A(V_R) > B$, which means that in the initial stage Landau damping would be accompanied with the cyclotron damping, and only after a certain time, when $A(V_R)$ exceeds B , would cyclotron growth occur.

This mechanism may play a significant role in the generation of natural and artificially stimulated very low frequency (vlf) emissions. If a wide spectrum of oblique whistler turbulence³ exists in the magnetosphere for a period of the order of the Landau resonant quasilinear relaxation time, a ledge is likely to form over the entire disturbed region in the velocity space. The whistler dispersion $c^2 k^2 / \omega^2 = \omega_p^2 / \{ \omega (\Omega \cos \theta - \omega) \}$ relation shows that the phase velocity has a maximum, $c\Omega/2\omega_p$, at $\omega = \Omega/2$. Therefore, a particle with $v_{||}$ greater than this would not be in Landau resonance with the waves and would, consequently, lie outside the disturbed region (Fig 3). A particle with $v_{||} = c\Omega/2\omega_p$ would gyroresonate with a whistler mode wave with a frequency of $\omega = \Omega/2$, propagating anti-parallel to B .

The steep gradient in the curve of f against $v_{||}$ which is consequently formed at $v_{||} = c\Omega/2\omega_p$ would, therefore, be unstable to whistler mode perturbations at $\omega = \Omega/2$ propagating in the negative z direction as equation (4) suggests and wave amplification may be expected at this frequency. This amplification would, however, be delayed as $A(V_R)$ would take some time to exceed B in order to give a positive growth rate. The nature of these results would not be altered even if the initial distribution were assumed to have an anisotropy in pitch angle.

Very low frequency emissions occur more often at half the equatorial gyrofrequency than at other frequencies³, it is likely that the mechanism described here is one that favours emissions at that frequency.

Origin of the Naturaliste Plateau

LYING off the south-west coast of Australia (Fig 1) some 2,500 m below sea level is the broad, rectangular Naturaliste Plateau, which forms a relatively flat ledge half way between sea level and the abyssal plain. How the plateau came to be in this position, and whether its origin is continental or oceanic, are two questions relevant to the evolution of the south-east Indian Ocean.

Until recently the only data bearing on the origin of the plateau were seismic profiles recorded by RV Vema¹ and by RV Robert D. Conrad, which also obtained 2 m of Upper Cretaceous sedimentary rock² by gravity coring (RC8-56). Deeper core information was obtained in late 1972 by the Glomar Challenger at Deep Sea Drilling Project sites 258 and 264 (refs 3 and 4, and Fig 2). Preliminary study of DSDP data indicates that the plateau has been at its present depth since Early Cretaceous (Middle Albian) time, accumulating pelagic sediments, and 'has probably been uplifted since that time rather than having subsided'³.

DSDP 258 penetrated 525 m of marine sediment up to 105 Myr old, containing detrital units in the Early Cretaceous which may be volcanically derived and which support an oceanic origin. But a Miocene/Santonian unconformity

Fig. 1 Location of the Naturaliste Plateau (NP) in the south-east Indian Ocean BR, Broken Ridge, NR, Ninety-east Ridge, WB, Wharton Basin, KC, Knox Coast, BP, Bruce Plateau, KR, Kerguelen Ridge, PB, Perth Basin Bathymetric contours in km after McKenzie and Solater¹¹

which represents a break of 70 Myr was encountered only 100 m below the seafloor and may be related to the final separation of Australia and Antarctica in Middle Eocene time. In the Robert D Conrad core (RC8-56) an unconformity separates Pleistocene and Turonian beds.

DSDP 264 near the southern edge of the plateau penetrated 215 m of carbonate sediment and bottomed in an undated volcanoclastic conglomerate containing both acid and basic volcanic rocks. The Tertiary/Cretaceous unconformity at the other core sites is here represented by three unconformities spanning late Miocene/late Eocene, early Eocene/mid-Palaeocene, and mid-Palaeocene/Cenomanian times. The erosion causing these shallow unconformities seems to have been less severe at the margins of the Plateau, as evidenced by the presence of Eocene and Palaeocene sections at site 264.

The first systematic survey of the area was achieved when the Australian Bureau of Mineral Resources (BMR) completed a series of 13 profiles over the plateau in December 1972. This was part of BMR's survey of the Australian continental margin using continuous gravity, magnetic, seismic, and bathymetric recording at a line spacing of 30 nautical miles. A preliminary study of these data together with previous information suggests a continental origin for the plateau.

The western and eastern halves of the Naturaliste Plateau differ significantly in bathymetric, seismic, and magnetic characteristics. The western half is the shallower and is characterised by shallow seismic basement and intense magnetic anomalies. The basin-like eastern area has thick sediments and less intense magnetic anomalies. Along the southern and parts of the western margin, but not along the northern margin, scarp-like bathymetric features suggest faulting in the basement. Elsewhere the seismic results show that the plateau sediments are not faulted or folded. The thickest sedimentary sequence is in the north-west

corner and in the low area to the east, where at least 2 km of sediment is present.

The Tertiary/Cretaceous unconformity is too close to the sediment-water interface at drilling sites 258 and 264 for detection on BMR seismic records. But three deeper unconformities were revealed. All four (A, B, C, and D) are shown on the cross section along XX' shown in Fig 3. The Tertiary/Cretaceous unconformity (A), detected in all three plateau cores, also occurs at Broken Ridge and Wharton Basin Sites³, and is of regional extent. Unconformity B extends over the whole plateau and truncates unconformity C, restricting it to the eastern part. The sediment/acoustic basement unconformity (D) is most readily identifiable in the areas of thin sediments in the west.

The well stratified sequence above unconformity B constitutes about half the total volume of sediments evident on the plateau and shows several local unconformities. Its thickness ranges from 200 to 1,100 m, assuming a sediment seismic velocity of 2.0 km^{-1} and DSDP data indicate that it is largely of Cretaceous age with only about 100 m of

Fig. 2 Bathymetry of Naturaliste Plateau, BMR traverses and core locations RC8-56, core by RV Robert D Conrad, 258, DSDP core site 258, 264, DSDP core site 264. Bathymetric contour interval 200 m.

Miocene and younger beds. Most sedimentation on the plateau, therefore, preceded the separation of Antarctica and Australia in Eocene time.

DSDP 258 was near the pinch out between unconformities B and C, and bottomed just short of C in a thick sequence of Albian clays and glauconitic sands. Thus, the beds between B and C, which reach a thickness of 700 m in the deep eastern area, are evidently these Albian clays. On the seismic sections they are largely transparent, but stratification becomes increasingly evident northwards.

Unconformity C seems likely to be Neocomian because it is close to the Albian clays at the bottom of DSDP 258 and because prominent prior tectonic activity known in the area took place in the Perth basin within Neocomian time. Jones and Pearson⁵ believe this to be the time when India became detached from the west coast of Australia during the breakup of Gondwanaland. But recent DSDP data from site 259 in the Perth Abyssal Plain indicated that this fracturing continued throughout the Cretaceous⁶. The basalt at the base of DSDP 259 was dated as Neocomian.

Below unconformities B in the west and C in the east are well stratified sediments ranging in thickness from 0 to 1,000 m. In the west they are draped over the basement, in the east they extend to the limit of seismic penetration. They are only gently folded and faulted, and were deposited before the Cretaceous activity.

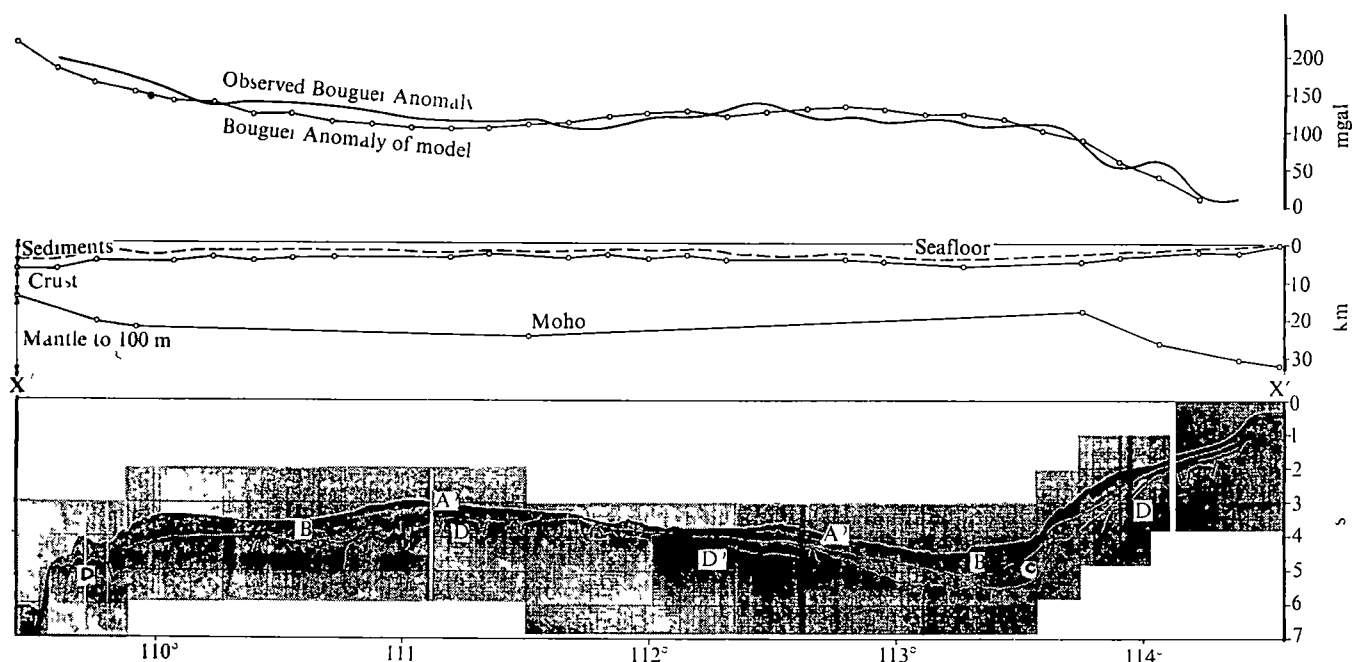

Fig. 3 Bouguer anomaly crustal model of the Naturaliste Plateau and seismic interpretation for section XX'. Densities used in gravity model: mantle 3.45 g cm^{-3} , crust, 2.85 , sediments, 2.20 . Standard crust for south-west Australia taken as 31 km thick after Mathur¹². A, B, C, D, are unconformities ↓ DSDP site 258

Acoustic basement is more visible on the seismic records from the western parts of the plateau, where sediments are generally thinner than in the east. Basement topography resembles a block-faulted and eroded plateau. Occasional reflection events below the basement unconformity suggest that the sequence is sedimentary, and this may be supported by the lack of strong reflectivity contrast with overlying sediments in some areas. Elsewhere there are features in the seismic sections showing intrusive form.

The magnetic anomaly pattern is more disturbed in the west, indicating a shallower magnetic basement than in the east. The high frequency and amplitude of magnetic features in the west suggest that the basement in this region is a complex of basic igneous and metamorphic rocks. This, together with the seismic evidence, points to a basement of metamorphosed sedimentary rock with basic igneous intrusions.

The Bouguer anomaly model showing the best fit with observed gravity is illustrated in Fig. 3. Crustal thickness is about 22 km , intermediate between continental and oceanic thicknesses, and is a further indication that the plateau was not originally an oceanic feature. A similar thickness was found⁷ under Broken Ridge from seismic refraction surveying in 1962 and it was suggested then that this feature is continental and may have been contiguous in the past with the Naturaliste Plateau and the Western Australian Shield.

BMR and DSDP data indicate that most of the plateau sedimentation preceded the separation of Australia and Antarctica and a large part was almost certainly pre-Cretaceous. The sediments were deposited on a basement of metamorphic rocks, and have remained tectonically undisturbed except along the southern and western margins. It is concluded that the plateau is of continental origin and existed as part of the continental mass of Gondwanaland in essentially the same position relative to Australia that it occupies today. Location of marginal scarp features suggests that there were landmasses along its southern and western margins, but not along its northern margin.

The reconstruction of Gondwanaland by Veevers *et al.*⁸ places India against the south-west coast of Australia and the Naturaliste Plateau some 500 km north of its present position. The reconstruction was based on evidence that the Perth Basin was within the interior of Gondwanaland up to the earliest Cretaceous. The BMR and DSDP data cast doubts on this reconstruction. The western basement block of the plateau could not have moved great distances horizontally relative to Australia since the deposition of the sediments without causing sedimentary deformations in the east that would be unmistakable in seismic records.

In the fit of Australia and Antarctica proposed by Sproll and Dietz⁹ the Naturaliste Plateau lies against a similar Antarctic marginal bathymetric feature known as the Bruce Plateau, offshore from Knox Coast. Rocks outcropping on Knox Coast are shown on the Geological Map of Antarctica¹⁰ to be Precambrian gneisses and schists of granulite facies. As suggested by the geophysical evidence such rocks are more likely than oceanic igneous rocks to form the basement of the Naturaliste Plateau. There is reason to believe, therefore, that the plateau once formed part of the Gondwanaland continental shelf (which explains the intermediate crustal thickness) abutting the Bruce Plateau. It broke away from Antarctica in the initial rifting which formed the southern Australian continental scarps and thereafter it remained attached to the Australian crustal plate.

The contribution of palaeosoil to Egyptian lithostratigraphy

THOROUGH examination of the contact between the basement complex (mainly Precambrian) and the overlying Nubia Sandstone (Upper Cretaceous) in seven localities in the Eastern Desert of Egypt (Fig 1) has revealed the existence of a well defined lateritic palaeosol capping the former rocks. Previously, mention has only been made¹ of a local kaolinised surface of the basement rocks and the lateritic palaeosol has been neglected in the lithostratigraphy²⁻⁴. The nature, thickness (4-10 m remaining after erosion) and the lateral extent of the soil over a wide variety of rock types necessitates, however, the introduction of a separate unit, which we suggest is called the 'I'byan Soil'. This palaeosol may cover a large area of Egypt and we suggest that the same nomenclature is used at all localities where the soil has lateritic affinities.

At the type locality, about 1 km north of the 97-km post east of Idfu (longitude 33° 44'E and latitude 25° 2' 30"N), the 'I'byan Soil' is 10 m thick and caps the Barramiya Serpentinities (Fig 2). In other localities it caps either old volcanics (Fig 1, locality 2), arenites of the

Fig 2 The succession at the type locality

Hammamat Group (Fig 1, locality 3), granodiorite (Fig 1, locality 4) or metasediments and metavolcanics (Fig 1, localities 5-7). The exact nature of the weathering of the basement rocks before the sandstone was deposited is now being studied through detailed geochemical and mineralogical analyses.

Decreased global rainfall during the past Ice Age

We have made a synthesis of atmospheric conditions for 20,000 yr BP based on fairly standard palaeoclimatological data and procedures. From mean zonal conditions at 20° latitude intervals from 80°N to 80°S we have computed radiative heating rates and the energy balance of atmospheric columns. We find that net cooling of the atmosphere by radiative processes was smaller at 20,000 yr BP than it is now. The total heating of the air, which sums to zero in the annual average except during periods of climatic change, is the sum of heating by latent heat liberation, heating by conduction and convection from the boundary layer, and radiative cooling (see for example Fig 7 in ref 1). Because the change in radiative cooling is comparable to boundary layer heating itself, we postulate that the decrease in cooling is accompanied primarily by a decrease in heating from rainfall and therefore that global rainfall was smaller at 20,000 yr BP than it is now. Examination of the magnitudes of the three components suggests that the decrease in rainfall was about 10%.

Details of the palaeoclimatic reconstructions will be published elsewhere but for completeness we state here the chief assumptions made and give the radiative cooling rates found

Surface air temperature maps for January and July were synthesised from observation of oxygen isotopes in ice cores, observations of tree lines, snow lines, pollen distributions and foraminifera distributions. Variation of temperature in the vertical was assumed to have the same form as today. Specific humidity was taken as a function of temperature only, the relationship in the troposphere being based on present-day observations. Stratospheric moisture and ozone concentrations were taken as identical to present-day values. Carbon dioxide was assumed to have a uniform distribution of 320 parts per million by volume. Cloud was assumed to be absent everywhere. A set of zonally averaged albedo values was drawn up from a consideration of the nature of the surface at each point on a $10^\circ \times 10^\circ$ grid. Radiative heating rates, containing contributions from both the solar and terrestrial portions of the spectrum, were computed following the technique devised by Rodgers² and modified by Dopplack³. Meridional cross sections of these rates were drawn up and integrations performed to obtain the total cooling of the air by radiative processes. These integral values, for the present atmosphere with cloud and without cloud and for the 20,000 yr BP synthesis without cloud, but with and without the albedo change, are shown in Table 1.

Table 1 Integral over the entire atmosphere of the net radiative cooling rate

	Present day		20,000 yr BP	
	With cloud	Without cloud	No albedo change	New albedo
January				
Globe	10.4	11.2	10.6	10.4
Northern Hemisphere	5.9	6.1	5.6	5.6
Southern Hemisphere	4.5	5.1	5.0	4.8
July				
Globe	10.5	13.1	11.8	11.7
Northern Hemisphere	4.6	6.7	5.5	5.3
Southern Hemisphere	5.9	6.4	6.3	6.4

Units: 10^{20} calorie d^{-1}

The present-day values show greater cooling without cloud than with cloud. Inspection of the cross sections shows that when the cloud is removed some regions at middle latitudes alter from slight radiative heating to radiative cooling. It therefore seems reasonable to interpret this difference as due to the blanketing effect of the cloud. When we compare the results without cloud for 20,000 yr BP and the present, it is evident that there is a smaller net cooling at 20,000 yr BP, substantially all due to changes in the Northern Hemisphere. Most of this change is due to temperature and specific humidity changes, rather than to albedo changes. The latter influences the solar input radiation to the ground-atmosphere system but has no effect on the terrestrial radiation lost to space. Treating the air alone, there is less cooling in the 20,000 yr BP synthesis because temperature and moisture content were both lower.

The air itself is able to maintain an annual equilibrium temperature because the net radiative cooling is counteracted by latent heat liberation and boundary layer heating (see Fig. 7 of ref. 1). These values are respectively about 9.0 and 1.5×10^{20} calorie d^{-1} for the present day atmosphere. A decrease in radiative cooling of about 1.0×10^{20} calorie d^{-1} , for the 20,000 yr BP synthesis, must have been accompanied by a decrease in net heating by the same amount. We postulate that a large fraction of this decrease occurred in the latent heat liberation term and that the rainfall was therefore smaller, by roughly 10%. The values in Table 1 suggest that most of this change occurred in the Northern Hemisphere.

There have been many discussions in the past when it was argued that Ice Ages were 'pluvials,' which had the connotation of additional rainfall. The above comments suggest that rainfall was less then than now. Recently some palynological records from the tropics have also been interpreted to imply that 20,000 yr BP was actually a drier time than the present⁴.

Kraus⁵ has also argued for a decreased rainfall based upon a presumed lower evaporation at 20,000 yr BP than at present, our argument reaches the same conclusion from an independent line of reasoning.

Glacial climates in the eastern tropical South Pacific

RECENT attempts to explain the glacial aridity at upper elevations in the Galapagos Islands have failed to take into account either concurrent events in neighbouring areas¹⁻⁶ or modern causes of climate. Yet, any reconstruction of the glacial climatology of the South Pacific must be consistent with all these data. Recognised glacial features of the region that must be taken into consideration and the empirical evidence which supports them include: increased upwelling along the equatorial divergence (enhanced plankton production⁷, simultaneous build up of guano⁸), upper elevation (650 m) aridity relative to the present in the Galapagos Islands (dated palaeomicrofloras⁹), increased precipitation above 2,000 m along the western slopes of the Peruvian Andes (deposits of oxides^{9,10}, traces of humid cycle stream cutting and scouring of alluvium⁹⁻¹¹, remains of sheet flooding at the base of the mountains^{9,10}, a disproportionate lowering of the west facing glacial snowline¹², relics of formerly more continuous plant and animal distributions^{13,14}), continuous aridity throughout the Pleistocene along the Peruvian coast (unbroken sequence of arid cycle processes⁹⁻¹¹), and exposure of large areas of the western Indo-Australian region following the 100-120 m sea level drop¹⁶ (fossil terraces^{16,17}). It can be deduced from the position of this exposed land that the modern pattern of vernal mixing of water from the eastern and western Pacific could not have taken place¹⁷ and that the eastern Pacific anticyclone did not, therefore, weaken in the glacial summer¹⁷. Thus, the pressure gradients between the two sides of the ocean would have remained fixed throughout the year and the eastern anticyclone and the south-east trade winds would have retained high intensity in both summer and winter.

At present, the low elevations of the Galapagos receive no moisture for most of the year and the upper elevations (1,000-1,700 m) are at best, covered by fog^{1,18,19}. The fog zone is the result of a temperature inversion brought about

Fig 1 Schematic representation of modern day climate along the coast of Peru at approximately 12°S latitude (adapted from Bowman²²). *a*, Winter conditions with garua (fog) along the coast, and Andean summits clear, *b*, summer conditions with thundershowers and rain at high elevations and clear weather along the coast

by the cooling, compression and drag of the lower part of the air mass crossing the cold equatorial upwelling on its way to the Galapagos^{18,19}. Rains occur in the spring when the eastern Pacific pressure system weakens and permits the invasion of warm air masses from the north. This southern penetration of warm northern air constitutes the normal summer movement of the Intertropical Convergence Zone (ITCZ). An abnormally pronounced penetration and its accompanying storms is commonly called 'El Niño'^{20,21}.

In western Peru, modern rainfall patterns are also seasonal but are caused by semiannual changes in the temperatures of the land (t_l) relative to that of the bordering ocean (t_o). In the southern winter, onshore winds are very cold, having blown across the Peru Current and the coastal upwelling²⁰⁻²². These winds hit an equally cold or colder coast ($-3^\circ\text{C} < t_l - t_o < 1.5^\circ\text{C}$) lose their velocity and essentially stagnate in the form of the famous garua (fog) of the coastal hills²² (Fig 1a). Throughout this period, the high slopes of the Cordillera are sunny and dry. During the southern summer, the onshore winds are only slightly warmer than in winter (between 1° and 4°C , see refs 20, 21, 22) because they still cross the Peru Current and the coastal upwelling. The coast, however, heats up considerably (2° – 6°C) as the Sun moves south, resulting in a large land-ocean temperature difference ($1^\circ\text{C} < t_l - t_o < 6^\circ\text{C}$). The net effect of the cold onshore breezes hitting the warm coast is that the air is heated, absorbs energy and increases in velocity as it moves toward the nearby Andes. The strength with which the air hits the mountains triggers an unstable rapid rise. Condensation and thundershowers occur when the air reaches about 2,000 m (Fig 1b). In contrast to the fogs of winter, summer is clear along the coast.

The simplest model of glacial climatology should explain all of the ice-age features in the tropical South Pacific without requiring any *ad hoc* postulations of phenomena beyond those currently operative. Yet previous hypotheses

disregarded the implications for neighbouring areas or theorised major changes in the climatic pattern. Thus, the suggestion that the increase in moisture along the upper Andean slopes was caused by a weakening of the Peru Current^{9,10} or the coastal upwelling⁸ is unsubstantiated and overlooks the fact that decreases in the strengths of these currents would have allowed an invasion of warm water from the north and caused increased precipitation in the Galapagos and along coastal Peru. A similar hypothesis², that the glacial ITCZ remained south of the equator throughout the year, is inconsistent with arid conditions in the Galapagos and along the coast of Peru. The converse theory, that the ITCZ remained north of the equator during the year¹ does not seem likely on theoretical grounds³ and would have caused dry 'winter' conditions to prevail for almost 12 months along the high Andes. A recent analysis of correlations between surface sea temperature and the lack of rainfall in the Galapagos Islands led to the postulation that increased upwelling at the zone of equatorial divergence caused the aridity of the islands², but the study did not explain the causes for increased upwelling and similar reasoning was not extended to areas outside the zone of the divergence.

The model proposed here incorporates this most recent observation, accounts for all of the documented glacial events in the tropical South Pacific, allows for local climatic anomalies near upwellings and is based solely on substantiated changes in atmospheric conditions and modern patterns of climate.

Wind intensity and high atmospheric pressure were maintained throughout the year because of the prevention of the summer relaxation of the eastern Pacific anticyclone¹⁷ and the northward movement of the westerlies⁴⁻⁶ which resulted in compression of the south-east trade wind system. This year long maintenance of high atmospheric pressure and intense circulation led to correspondingly intense ocean currents and vigorous upwellings at the zone of equatorial divergence and along the Peruvian coast. Thus, waters as cold as, or colder than, those of the present winter were being brought to the surface or from higher latitudes near the Antarctic Ice Cap continuously throughout the year. Estimates from changes in carbonate composition and in the distributions of foraminifera^{23,24} indicate a cooling of ocean waters (5° – 6°C) off the coast of Peru. Estimates of low latitude, low elevation, land surface temperature depression are usually less than 3°C (ref 16). Along the Peruvian coast, unequal land-ocean cooling would have meant that temperature differences in a glacial winter would have approximated the present summer difference ($1^\circ\text{C} < t_l - t_o$). The modern summer pattern of arid lowlands and thundershowers at upper elevations, would have continued during most of the year. A corresponding increase in aridity at upper elevations in the Galapagos produced by lowered sea surface temperatures along the equatorial divergence was discussed by Houvenaghel².

It must be emphasised, however, that in the tropics, most climatic changes probably occurred near the beginning or the end of traditional temperate latitude glacial cycles, when ocean and land surface temperature differences were at a maximum and caused the most important effects of the Pleistocene in low latitudes—repetitive cycles of aridity and humidity¹³.

Interaction of sodium dodecyl sulphate and polyethylene oxide

AN increase in the concentration of K_2CO_3 in Polyox WSR 205 causes a decrease in the drag reduction¹, this has been successfully correlated with lowered values of the intrinsic viscosity¹. Nonionic, water-soluble polypeptides can interact with sodium dodecyl sulphate (SDS) to form complexes², and above a certain concentration the reduced viscosity of some of these polymers is increased. The immediate implication is that if such interactions also take place with polyethylene oxides of high molecular weight then changes in the observed drag reduction may occur.

Some sort of soap-polymer interaction does occur (Fig 1), at all polymer concentrations the drag reduction is significantly improved in the surfactant solution. The turbulent flow line of SDS alone was not measurably different from that of pure water. This seems to be the first evidence that the drag reduction of a polymer in a good solvent can be slightly improved by the addition of a third component to the system. For example, at intermediate concentrations of 7-10 parts per million (p.p.m.) of Polyox WSR 205 there is a 35% increase in the observed drag reduction (Fig 1). The observed increase in drag reduction is similar to that which occurs at the lower Reynolds number of 6,000 (Fig 2). The increase in percent drag reduction over a similar concentration range is again of the order of 35%. The decreased effectiveness of the polymer-soap complex as the Reynolds number, Re , is increased is summarised in Table 1 where the intrinsic concentration, $[c]$, provides a measure of the efficiency of the drag reduction. It is obvious that the large increase in intrinsic concentration for the polymer-soap complex as compared with the polymer alone suggests that the complex

Fig. 1 Drag reduction against concentration for Polyox WSR 205 in water (O) and 0.2% SDS solutions (□) a, At $Re = 9,000$, b, at $Re = 6,000$

is breaking up at higher shear rates or stresses. This may not be too surprising in itself as aqueous drag reducing soap systems involving additional simple substances such as electrolytes³ and certain amines⁴ have exhibited stress-controlled drag reduction.

A ready explanation for this polymer-surfactant behaviour has been suggested². Apparently, in the present case hydrophobic bonding takes place between the polymer and the hydrocarbon tail of the surfactant. As sufficient surfactant becomes bonded to the polymer, electrostatic repulsion between bound surfactant ions on the polymer backbone causes the polymer coil to expand. Essentially, then, in the present case the equivalent of a polyelectrolyte is created through polymer-surfactant interaction. The dependence of such interactions on the nature of the surfactant and the polymer will be the subject of future work.

Bond energy of the IO radical from molecular beam reactive scattering measurements

THE bond energy $D_0(\text{IO})$ of the IO radical is not reliably known. An early estimate, $D_0(\text{IO}) = 44 \text{ kcalorie mol}^{-1}$, was derived by Gaydon¹ from the IO emission spectrum of the CH_3I flame. Since this value was obtained by Birge-Sponer extrapolation of only five vibrational levels of the upper $\text{IO}(^2\Pi)$ state, it is not expected to be very accurate. The same spectrum was studied by Ramsay² in absorption by flash photolysis of O_2/I_2 mixtures. Birge-Sponer extrapolation of six bands gave $D_0(\text{IO}) = 42 \pm 5 \text{ kcalorie mol}^{-1}$. But more accurate extrapolation² for ClO and BrO using twenty bands showed that extrapolation from a small number of low lying levels leads to unreliable results. A rigorous upper bound $D_0(\text{IO}) < 62.8 \text{ kcalorie mol}^{-1}$ was determined from predissociation of the upper $\text{IO}(^2\Pi)$ state.

A value $D_0(\text{IO}) = 57 \pm 6 \text{ kcalorie mol}^{-1}$ was estimated by Sugden³ by photometry of the IO emission spectrum from a $\text{O}_2/\text{H}_2/\text{I}_2$ (1%) flame equilibrium. Two estimates^{4,5} have been made by extrapolation of the RKR potential curve of the upper $\text{IO}(^2\Pi)$ state with model potentials; one⁴ supporting the higher flame equilibrium value and the other⁵ supporting the lower Birge-Sponer value.

Recently, preliminary reports⁶⁻⁸ of O atom reactive scattering by ICl have shown an important reaction path to be

In our experiments, a crossed molecular beam apparatus⁹ with an electron bombardment mass spectrometer detector was used. The O atom beam was produced from a low pressure (~ 1 torr) microwave discharge through O_2 . The discharge region was separated from the beam source slit by ~ 60 cm of Pyrex tube. This configuration results in a low temperature ~ 350 K atom beam and suppresses $\text{O}_2(^1\Sigma_g^+)$ metastable molecules. The ICl cross beam issues from a supersonic nozzle source and has a narrow velocity distribution ($\sim 20\%$ full

width at half maximum). The most probable reactant translational energy was $E = 0.8 \text{ kcalorie mol}^{-1}$. The distributions of IO product velocities have been measured by a computer time-of-flight system over a range of laboratory scattering angles. Analysis of the full experimental data shows that the reaction proceeds by a long-lived complex mechanism.

The distribution of IO product translation energy in centre of mass coordinates is most accurately determined by observation of the IO velocity distribution along the direction of the centroid vector in laboratory coordinates. The IO flux density distribution measured at laboratory scattering angle $\Theta = 79^\circ$ (nominal centroid vector at $\Theta = 78^\circ$) is shown by open circles in Fig. 1. The distribution for the long-lived collision complex, predicted by a model¹⁰ based on RRKM theory of unimolecular decomposition, is also shown by a solid curve in Fig. 1. Agreement with the experimental data is obtained for a reaction exoergicity $\Delta D_0 = 3.4 \text{ kcalorie mol}^{-1}$. Using¹¹ $D_0(\text{ICl}) = 49.6 \text{ kcalorie mol}^{-1}$, we obtain $D_0(\text{IO}) = 53 \pm 3 \text{ kcalorie mol}^{-1}$.

This value of $D_0(\text{IO})$ also gives good agreement with our time of flight measurement of the $\text{O} + \text{I}_2 \rightarrow \text{IO} + \text{I}$ reaction. But the exoergicity, $\Delta D_0 = 17.4 \text{ kcalorie mol}^{-1}$, is greater for this reaction. Thus it does not provide as sensitive a test of $D_0(\text{IO})$ as the almost thermoneutral $\text{O} + \text{ICl}$ reaction.

Unique form of filamentous carbon

CONSIDERABLE interest has been shown in the formation of carbon filaments from the catalytic decomposition of gases over metal surfaces at about 700°C (see refs 1, 2). Detailed studies have been chiefly confined to the behaviour of pure metals, but technically and industrially the effect of alloying elements is also important. We have studied how additives to an iron catalyst modify the filament growth process during decomposition of acetylene. With acetylene decomposed on a Pt/Fe alloy a new mode of filament growth was identified in which the complete detachment of a catalyst particle from the surface of the metal was not a necessary prerequisite for growth³. Here we describe the effect of tin on the growth of

Fig. 1 Scanning micrograph of a spiral filament produced from Sn/Fe catalysed decomposition of 5 torr acetylene at 800°C.

filaments from the iron/acetylene system. The experimental technique used in this work, controlled atmosphere electron microscopy, has been described elsewhere⁴.

Significant deposit growth was only observed at temperatures above 800°C with tin coated iron foils in 5 torr acetylene and

Fig. 2 Variation of spiral length with spiral diameter.

was preceded by an induction period of about 10 min at this temperature. On pure iron, deposits grew at temperatures as low as 650°C under otherwise similar conditions. Pure tin did not produce a deposit. In contrast to the growth on pure iron, which became autolytically poisoned after a few minutes, growth still continued on Sn/Fe after more than 2 h and poisoning was never observed. The deposit was filamentous, a common form of growth from acetylene^{1,2}, but the filaments were nearly all spirals with a constant pitch (Fig 1). Although spiral filaments have been observed in other systems^{1,5,6} they are rare and the production almost exclusively as spirals is unusual.

Fig. 3 Mode of formation of branched filaments.

The average pitch θ , can be obtained from a plot of the spiral length, l , against the diameter of the spiral, d ;

$$l = \pi d \tan \theta$$

and is found to be 30° 41' (Fig. 2).

Two filaments grew from each particle in opposite directions and it was not possible to discern the shape of the particle. The two filaments grew at identical rates and any kinks or imperfections in one were reproduced in the other so that the two filaments were exact enantiomorphs except for the handedness of the spirals which, viewed from the particle, were opposite handed in every case. Branching of filaments was common and seemed to be the principal means of relieving the stress created by the fact that filaments were often forced against the mass of deposit in two directions. When this stress became too great the particle was squeezed out from between these two

filaments and began to propagate a new pair, (Fig. 3). It is not possible at present to give a detailed account of the processes which constrain filaments to grow in this manner although it is certainly associated with the structural characteristics of the catalyst particle.

Ancient boomerangs discovered in South Australia

DURING excavation in a South Australian peat quarry in January 1974, a wooden tool industry was found buried in basal peat formed between $10,200 \pm 150$ BP (ANU-1,292) and $8,990 \pm 120$ BP (ANU-1,293). Chert tools and chipping debris associated with swamp side encampment were also recovered from shoreline clays and underlying muds. Three implements associated with this industry are complete boomerangs (Fig. 1), suspected of being made from *Casuarina stricta* (Drooping Sheoak), a species growing above the swamp today. Although exact ages for the boomerangs are still to be determined, the finds provide the oldest evidence of the boomerang in the world and the collection as a whole is one of the most technologically complete in the Australian archaeological record. The collection of more than 25 wooden implements includes a simple short spear, at least two types of digging stick, and a barbed javelin fragment carved from a single piece of wood. Although several other implements were recovered complete, their functions are as yet unknown.

Featuring robust working edges made on large flake cores, typically worked into convex steep-edged scrapers, the stone tool industry conforms well to the 'Australian core-tool and scraper tradition' described for the 26,000-yr-old Lake Mungo industry^{1,2} and to which Pleistocene components at Keilor, Kenniff Cave, and Burrill Lake might also be assigned. Citing ethnographic examples and microscopic evidence, several researchers, particularly Jones³, have ascribed to these forms heavy wood-working tasks such as planing, cutting, debarking, and scraping—precisely the tasks Wyrie Swamp stone tools are believed to have performed. But, whereas food preparation/procurement roles are suspected of being present in the lithic technology, no direct dietary or faunal evidence was uncovered.

Current palaeobotanical studies of the peat deposits in the region made by John Dodson at the Australian National University (ANU) indicate trends in peat accumulation which appear to correlate with prehistoric utilisation of the bog. Principal Aboriginal visitation took place during an initial shallow water phase characterised by fluctuating wet, and occasional dry, episodes dated to between 10,200 and 9,000 yr ago. During this period, when the swamp was small, its shoreline became the scene of numerous tool-making and hunting and gathering activities centred on resources at the water's edge. However, 9,000 yr ago an increasingly more permanent water stand rose to cover most of the gently sloping bank, burying the shoreline debris and displacing tool-making on to the adjacent steep dune slopes. Evidence for subsequent use of the swamp appears

Fig. 1 This fragment of a fourth boomerang from Wyrie Swamp has been identified as *Casuarina stricta* root. Measuring 11 cm, it has been treated with polyethyleneglycol and freeze-dried.

infrequently until $7,930 \pm 160$ BP (ANU-1,377), possibly in response to the relocation of aquatic plant resources.

We can therefore see the Australian Aborigine emerging from the Pleistocene equipped with a tool kit as vital to the exploitation of the local environment then as it was yesterday, and just as complex. Exactly how long this technological tradition previously existed is as yet unknown but the possibility that the boomerang soared over the shores of Lake Mungo 16,000 yr earlier seems more plausible as a result of discoveries at Wyrie Swamp.

The reduction of mono-coordinated molecular nitrogen to ammonia in a protic environment

WE have reduced ligating molecular nitrogen (dinitrogen) to ammonia in yields of up to 90% at a single metal site. This reaction is important for its possible application to our understanding of the chemical mechanism of the reduction of dinitrogen to ammonia by nitrogenase, where the reduction may occur at a single molybdenum ion site¹. Our reaction occurs when compounds of the type $[M(N_2)_2(PR_3)_4](I)$ ($M = Mo$ or W ; $R =$ alkyl or aryl) are treated at room temperature with sulphuric acid in methanol solution:

This reaction was performed in a vacuum so that the evolved gases could be analysed and measured. On mixing the reagents, one molecule of nitrogen gas was rapidly evolved with a trace of dihydrogen. The remaining dinitrogen was spontaneously

§ Run at about -2°C , all other reactions at 20°C .

reduced to ammonia together with some hydrazine, presumably also with concomitant oxidation of the metal M.

The highest yield of ammonia (90%) was obtained from *cis*-[W(N₂)₂(PMe₂Ph)₄] in methanol. In a non-protic solvent, tetrahydrofuran (THF), the yield of hydrazine was substantially increased, but that of ammonia was halved. In aqueous methanol, the yield of ammonia was also lower, possibly due to the lack of homogeneity in the reaction mixture. The compounds examined, the effect of solvents and yields obtained are listed Table 1.

The metal-containing products from the tungsten reactions were insoluble blue solids, but with molybdenum the reaction mixture remained as a yellow-brown solution throughout. These metal products also contained some nitrogen when the solvent was THF.

We have already shown² that the ditertiary phosphine complexes, *trans*-[M(N₂)₂(Ph₂PCH₂CH₂PPh₂)₂] (II; M = Mo or W), when treated with hydrogen bromide, quantitatively form complexes of diazene, HN=NH; however, the diazene ligand could not be protonated or reduced any further in a protic solvent, except perhaps in trace amounts. Sulphuric acid has similarly given a quantitative yield of hydrazido-(2-) complexes, tentatively formulated as [M(SO₄H)(N-NH₂) (Ph₂PCH₂CH₂PPh₂)₂] SO₄H on the basis of their infrared spectra and analysis; however, no further protonation occurred to give a significant quantity of ammonia or hydrazine. Very low yields of ammonia have also been claimed from the treatment of the complex (II; M=Mo) with iron-cluster compounds, for example, [Fe₄S₄(SEt)₄]³⁻ in THF followed by acid³.

The difference between the complexes (I) and (II) which allows the reduction to proceed in the former but not in the latter, is, we believe, the ability of (I) to lose a molecule of ligating tertiary phosphine. This would allow the attack of a second sulphate (or hydrogen sulphate) ion at the metal centre, increasing its electron density. The consequent flow of electronic charge into the N₂H₂ ligand would then trigger its further protonation and reduction to hydrazine and then to ammonia.

As far as the natural system is concerned, these reactions show that molecular nitrogen can be reduced at a single metal site in a protic medium with negligible discharge of dihydrogen or displacement of dinitrogen by hydride ligands. It may also be significant, in view of the special role of molybdenum in nitrogenase, that the reduction of mono-coordinated dinitrogen has been found for the first time in molybdenum and tungsten complexes.

The most commonly proposed mechanisms of reduction involve dimetal sites^{4,5}; and by protonation of dinitrogen-

bridged dimetal complexes, yields of ammonia and/or hydrazine of up to one dinitrogen molecule reduced for each dimetal unit have been obtained^{6,7}. Our system is the first observation of reduction, in a protic medium, of one molecule of dinitrogen per transition metal atom in a well defined complex. It shows that a monometal site is at least as likely as a dimetal site in nitrogenase.

In our reduction the metal must increase its oxidation state by six units ($\text{M}^0 \rightarrow \text{M}^{\text{VI}}$), all six electrons being fed from the metal into the ligating dinitrogen molecule. This great jump in oxidation state is highly improbable in any catalytic system such as that of the enzyme, but our reaction could provide a possible model for the feed of electrons from the metal atom into the dinitrogen molecule, on the atomic level, along the atom chain M-N-N. It also suggests that such feed of electrons and consequent reduction of dinitrogen, may be triggered by replacement of some 'soft' ligand on the molybdenum by a 'hard' one such as an oxygen ligand [for example, sulphate, phosphate, hydroxide or phenoxide (from tyrosine)]; the reverse replacement would occur during the metal reduction and dinitrogen pick-up stage of the enzyme action.

Control of aquatic weed by moth larvae

AQUATIC weeds use up nutrients in the water and so reduce the capacity of cultured areas to produce fish^{1,2}. Chemical, manual and mechanical control methods can be too

expensive³ and biological weed control is ecologically acceptable and more dependable.

The Chinese grass carp (*Ctenopharyngodon idella* Val.) has proved efficient in controlling many common aquatic weeds⁴⁻⁸. Some insects too may destroy particular aquatic weeds⁹⁻¹³ but their use for biological control has not received much attention. Philipose¹⁴ found that certain moth larvae were able to feed on the leaves of *Pistia stratiotes* L., a common noxious floating weed, but did not identify them or describe the infestation.

Here we report that the larvae of the moth, *Erastroides curvifascia* Hampson, feed specifically on foliar and stem portions of *P. stratiotes* (which is not eaten by grass carp or any other phytophagous fish) and describe their use as a potential biological control agent for the weed in fishery waters.

Field observations were made in a perennial pond (0.35 ha) with a dense infestation of *Pistia*. The numbers of larvae are high during the winter months (that is November to February) (water temperature: 22–26° C) and therefore the consumption of the host plant is also extensive during this period. The entire life cycle of the moth is completed within 27–35 d. The larval stage, which is the active feeding phase, accounts for more than 50% of the life span. The late instar larva pupate in the deep furrows of leaves and petioles of *Pistia* after feeding for about 7–9 d. The pupae metamorphose into adults in about 5–6 d.

Three sets of preliminary trials were conducted in plastic pools (capacity 500 l; surface area 6,943 m²). Field conditions were simulated by providing 50 kg of pond soil at the bottom and 200 l of pond water in each set. The weed density in the three plastic pools was identical, each receiving 1,650 g of fresh *P. stratiotes*. Two different densities of the late instar larvae, 86 m⁻² and 17 m⁻² of the surface area, were tried in the first and second pools respectively, the third being the control. The larvae in the first pool cleared 1,340 g of weed in about 30 d, and 1,230 g of weed was cleared in 40 d in the second pool. The control set recorded an increment of 960 g in weed weight at the end of 40 d reflecting the growth of *Pistia* in the absence of predation by the moth larvae. It was observed that in both the experimental sets the larvae introduced initially pupated after a brief period of feeding, resulting in the emergence of moths which immediately bred. The new early instar larvae caused most of the damage to the plants.

Our study indicates the possibility of using the larvae of *E. curvifascia* for controlling *Pistia*, as they largely satisfy the basic requirements of a potential control agent. The comparative ease with which the larvae can be transferred *in situ* to host plants and the way the moths readily breed in the laboratory suggest a wide scope for disseminating this important agent for the control of *Pistia* in fishery waters.

We thank Dr V. G. Jhingran, Director, Central Inland Fisheries Research Institute, Barrackpore, for his interest and the Director, Zoological Survey of India, Calcutta, for providing necessary facilities in identifying the moth.

Hornet nest architecture

ALL social wasps belong to the family Vespidae. This family is divided into the following three sub-families: the Stenogastrinae—prevalent in South-east Asia, the Polistinae—of almost worldwide distribution, and the Vespinae—including the more socially developed forms which are encountered primarily in the Northern Hemisphere¹. The comb constructed by these wasps is fastened by a pedicle to the roof of the nest^{2,3}. In the course of the season the combs attain optimal size and acquire a spherical or elliptical shape, curving upwards at the centre, much like an inverted mushroom. The pedicles are long enough to allow clear passage of wasps from one comb to another.

Here I report observations and experiments carried out to elucidate the way in which hornets acquire the spatial perception necessary for the construction of combs with such clear-cut architectonic lines.

Hornets (3 d old) were maintained in groups of 30–40 individuals in specially constructed wooden breeding boxes with one wall of transparent glass⁴. Observations were made on the comb-building activities of intact hornets as compared with those of hornets with variously amputated wings. The wings were treated in one of four ways: first, one pair of wings was amputated; second, both pairs of wings were amputated; third, same as the first but subsequent maintenance of the hornets for 3–4 d at a temperature of 8° C; fourth, same as the first but with supplementation of the diet with queen pheromones (C₁₆ lactose).

The standard diet in all the experimental breeding boxes was 30% sucrose solution *ad libitum* as well as daily quotas of wasp or bee pupae. Clumps of clay soil were introduced as building material for the wasps. All experiments were carried out in a vesparium whose dimensions are given elsewhere⁵ and in which the temperature was kept at 27–28° C, as optimal for hornet activity⁶, while the relative humidity was 65–70%. Each experiment was repeated ten times.

Hornets with intact wings, after several days in the breeding box, commence building pedicles which are suspended from the roof of the box and serve as foundations for combs that architectonically resemble those produced in nature. The combs are constructed one next to the other and in parallel to the roof. The initial combs are small, each consisting of 20–30 cells, but ultimately they merge to form a single, large comb the breadth of which is functional to and only slightly smaller than the breadth of the roof. At the lateral margins of the comb there are always narrow gaps between it and the frame of the breeding box which permit movement of hornets to and from the comb. Similarly at the top of the comb, because of the pedicles which suspend the comb from the roof of the breeding box, there is a narrow space which enables passage of the worker or queen hornets as in nature. The width of this gap is 1.5–1.7 cm.

Hornets which had one pair of wings amputated also constructed a number of combs, but their construction differed in the following respects. The combs were fastened by pedicles to the wall of the breeding box rather than to its roof, that is at right angles to the norm. They were built one beneath the other, rather than one beside the other; that is, along a vertical axis rather than in the customary horizontal placement. The vertical distance between two adjacent combs was about twice that in normal or natural construction (3.2–3.4 cm). The combs do not merge but

remain discrete and small, consisting of about 50–60 cells each (Fig. 1, lower three combs). The pedicle, which in the normal comb was a compact rod narrow at the middle and wide at both ends was in this case merely a single or double row of 2–4 cells which formed a narrow bridge between the wall of the box and the comb (Fig. 1). Oviposition into the cells which substitute for a pedicle never occurred, but the workers did oviposit into other comb cells and subsequently nursed the emerging all-male brood. Structurally, the single comb of wing-amputated hornets resembled a mirror half-image of a normal complete comb.

Hornets with both pairs of wings amputated constructed their combs as described before but without a pedicle, that is, the combs were constructed right against the wall of the breeding box. Cooling or pheromone-feeding of the wing-amputated hornets caused them to revert to normal comb construction. It is worth mentioning that both hornets with

Fig. 1 Lateral view of hornet combs. The topmost comb represents normal construction. The three bottom combs were constructed by hornets who had one pair of wings amputated. The pedicle in these combs is along the same plane as the comb itself rather than vertical to it.

intact or amputated wings built cells of the same size and invariably the cell apertures faced downwards.

I believe that the vertical distance between two adjacent combs constructed by wing-amputated hornets should be regarded as analogous (at a 90° displacement) to the horizontal distance between two adjacent combs constructed by hornets with intact wings. The results clearly indicate that comb construction by wing-amputated hornets is different from that by normal, intact hornets. The most prominent deviation in comb construction is the different spatial orientation of the combs, which suggests that the wing tips of hornets figure importantly in the spatial perception. Amputation of the wings seemingly causes a displacement of the sensory feedback of the spatial perception and thus apparently results in deviations or errors in the orientation of construction, in incorrect distances between adjacent combs and in unilateral comb architecture. A constructing hornet, while moving about at the construction site, acquires an awareness of its spatial orientation. Von Holst⁷ designated this awareness refference, implying such impulses arise because of movement of the organism. I have no reasonable explanation as to how pheromones induce habituation of the anatomical displacement in wing-amputated hornets, but it is possible that the cooling for several days retards or prevents the ripening of their ovaries and thus inhibits the building instinct without, however, curtailing their movements. Thus the moving hornet, in its unfamiliar asymmetric situation, is able to acquire the feeling of refference and within a few days learns to orient itself to the new spatial conditions by readjustment of the sensorial feedback.

In Vespinae, the tips of the wings of the workers usually extend close to or even slightly past the tip of the abdomen. In contrast, in Stenogastrinae, the wings are always relatively short, covering only the anterior segments of the abdomen. The combs of the latter vespids are comprised of a relatively small number of cells⁸ and lack a pedicle, being fastened directly to the substrate⁹ resembling those built by hornets with two pairs of wings amputated.

It is possible that amputation of the wings of Vespinae, as I have done with *Vespa orientalis* converts the spatial perception of these hornets to that commonly displayed by Stenogastrinae. There may also be a connection between the architectural building in the Polybiine (Polistinae) wasps—phragmocytarous as against stelocytarous—and the length of their wings.

Extraretinal control of vertical migration in fish larvae

MANY species of fish, including the Atlantic herring *Clupea harengus* and its larvae, undergo diel vertical migrations^{1,2}. In the herring and plaice larvae this migration has been shown

Fig. 1 The change in surface activity of normal and eyeless herring larvae in response to a reduction in ambient light intensity. Groups of 20 larvae were placed in seawater in an acrylic column (internal diameter 5.1 cm, water depth 117 cm) located in a light-tight box and illuminated from above by a 12 V 40 W tungsten lamp run at 12 V giving a light intensity of 10^2 lx at the water surface. The light beam passed through three glass heat filters then through one of a series of neutral density filters. The neutral density filters were located in a wheel which changed automatically every 15 min reducing the light by a factor of 10 to a final level of 10^{-9} times the original light intensity. A pair of matched thermistors in a balanced bridge circuit were inserted in the water column, 2 cm below the water surface, to record larval activity. Activity thus recorded has been shown to give an estimation of the number of larvae active at that level³. Larval movements detected by the cooling of the thermistors were recorded on paper for later analysis (activity only assessed during latter 10 min of exposure at each intensity). Herring and plaice larvae, both with eyes and in an eyeless condition, were tested in this apparatus. The eyes were removed surgically from anaesthetised larvae at a variety of developmental stages and as far as possible each group of experimental larvae was at the same stage. Within the range of larval stages tested the responses of the larvae were found to be comparable and the results have been pooled. The activity has been plotted as a percentage of the total activity to compensate for differences in activity level between experimental groups. The light intensity was measured with an EEL Microphotometer with a maximum sensitivity between 450 and 550 nm, the peak being about 510 nm. ●, Blind ($n = 10$); ■, controls ($n = 5$).

to be evoked by changes in light intensity³. Under laboratory conditions they move towards the water surface at dusk and return down the water column at dawn when exposed to natural light. Moreover this vertical migration can be evoked at any time of day by reducing, then increasing, the ambient light intensity³. The control of this behaviour is shown here to be at least partly mediated through extraretinal photoreceptors in the larvae of herring and plaice, *Pleuronectes platessa*.

Figure 1 clearly shows that the eyeless larvae respond to a reduction in light intensity greater than a factor of 10^{-3} by moving towards the water surface in a similar fashion to the control larvae. Also the activity, and hence the number of larvae at the surface, increases as the light intensity is further decreased. Although the activity patterns of eyeless and control larvae are not identical, they are similar enough to suggest that the same extraretinal photosense may be responsible in both conditions. Figure 2 shows that returning the light to its original intensity rapidly abolishes the surface activity of eyeless larvae, thus reversing the direction of migration.

At higher light intensities (Fig. 1) the normal larvae exhibit a high surface activity whereas the eyeless larvae remain lower in the water column. This initial response of the control animals appears to be phototactic. Blaxter⁴ has shown herring to be positively or negatively phototactic depending on the light intensity; and the range of intensities, over which this initial surface activity occurs, corresponds approximately to

that at which he observed positive phototaxis. Eyeless larvae are not phototactic over the range of light intensities 10^2 to 10^{-7} lx. Plaice larvae respond in a less marked but similar manner to herring larvae.

This correlation of the vertical migration of eyeless and control larvae is particularly interesting as it indicates that extraretinal photosensitivity plays an important role in the daily regulation of the behaviour of normal larvae. Moreover, the activity of the larvae, particularly at intermediate light intensities is influenced by the input of both the eyes and extraretinal photoreceptors. The retinal and extraretinal photosenses therefore seem to interact in producing the observed behaviour.

A suggestion that such interaction of photosenses may occur in adult fish may be seen in the work of Jones⁵. He demonstrated that minnows, *Phoxinus phoxinus*, are less active by day than by night when blind, whereas eyed fish in the absence of cover show the opposite pattern of activity. Where adequate cover is provided, however, the daytime activity of the eyed fish is considerably reduced and greater activity is displayed at night, especially observed at dawn and dusk. From this it can clearly be inferred that, as with the herring larvae, the observed behaviour results from retinally and extraretinally evoked behaviour.

Fig. 2 The response of a single group of eyeless larvae showing the rapid manner in which surface activity is decreased when the light is returned to its original level. The interval between the increase in light intensity and activity measurement was 20 min.

It would seem that the light intensity dependent behaviour in these two examples could be divided into retinally evoked phototaxis and an extraretinally evoked kinesis which cannot be separated in sighted larvae. Further work is in progress to study the interaction of the two photosenses in modulating the animal's behaviour. Nothing can be said at this stage of the location of this extraretinal photosense but attention is drawn to a recent paper on trout⁶ which showed their diel activity pattern to be relatively unaltered by the removal of both the eyes and the pineal gland.

Effect of absence of cochlear outer hair cells on behavioural auditory threshold

THE function of the two populations of sensory cells in the mammalian inner ear is not well understood. Anatomical evidence indicates that the inner hair cells (IHCs) and the outer hair cells (OHCs) play separate roles in the transduction of acoustic stimuli¹. Furthermore, there have been numerous proposals attributing different roles to the two hair cell populations in the production of the various cochlear potentials²⁻⁵. On the other hand, theoretical considerations and the interpretation of data from several experiments have led to suggestions of different types of interaction between the OHCs and IHCs⁶⁻⁸.

A common means of investigating the relative roles of the two groups of sensory cells is to destroy portions of one population, usually the OHCs, and assess the changes thus produced in various indices of cochlear function. A valuable tool in such studies has been the application of aminoglycoside antibiotics. These agents are specifically toxic to cochlear hair cells, OHCs being more vulnerable than IHCs at some cochlear locations^{9,10}. Independent measurements of OHC and IHC function have been obtained by treating animals with these antibiotics, thereby largely destroying the OHC population in parts of the cochlea, while leaving much of the IHC population intact. Electrophysiological recordings from the cochlea or the VIIIth nerve were then collected and compared with responses obtained from normal inner ears³⁻⁵.

The present study was undertaken to examine the function of the OHC and IHC more directly, by measuring the behavioural pure tone thresholds of animals treated with kanamycin. We were particularly interested in determining whether or not a characteristic audiometric pattern could be related to the selective destruction of portions of the OHC population.

Eight adult male chinchillas were first trained in a shock avoidance task similar to that developed by Miller¹¹. The shuttle-box, located in a small anechoic chamber, was calibrated at 54 points spaced equally about the cage. Results were averaged to determine sound pressure levels. Stable threshold curves were usually obtained within 3-5 d after the initiation of training. One threshold curve was collected in one session per day for each animal. Ten such curves were obtained before the commencement of kanamycin treatment, and averaged to produce a baseline measure of sensitivity from 100 Hz to 16 kHz. Normal thresholds were similar to those obtained by Miller¹¹.

The animals were injected subcutaneously with kanamycin (200 mg kg⁻¹ d⁻¹). This dosage was increased to 300 mg kg⁻¹ in two animals which were resistant to the drug. Daily threshold determinations were carried out and treatment was terminated when a significant shift in threshold was observed. When the threshold shift seemed to have stabilised, ten threshold functions were again obtained and averaged to produce a post-treatment measure of sensitivity.

Animals were then anaesthetised with urethane and paired, intracochlear electrodes were implanted in scala vestibuli and scala tympani of the basal turn, following which cochlear microphonic (CM) data were collected. Finally, both cochleae were perfused with osmic acid and prepared for histological examination either by the surface preparation¹² or the Araldite embedding technique¹³.

Initial shifts in threshold occurred at the highest frequencies, appearing after 6-35 d of kanamycin treatment. The increase in threshold spread towards the lower frequencies and stabilised within 7-15 d after termination of injections. One animal became totally deaf, within the limits of our equipment to determine, but died without electrophysiological or histological data being obtained. Two animals with relatively severe hearing loss became ill and were killed without collecting electrophysiological data. The remaining five animals survived from 3 to 5 weeks after treatment was terminated, before being killed. One

animal which suffered considerable IHC damage is not included in the discussion below.

Figure 1a and b shows the OHC counts and the shifts in behavioural threshold from six animals, respectively, arranged according to the severity of hair cell loss. Note that the behavioural manifestation of OHC loss in the basal region of the cochlea was a threshold shift at high frequencies; thresholds at low frequencies remained virtually unaffected. The agreement between the extent of OHC loss and the frequency region of threshold shift is quite good. To assess this agreement, the distance from the apical end of the cochlea at which 50% OHC loss occurred, and the lowest frequency at which normal thresholds were obtained, gave a correlation (Spearman Rank Order) coefficient $r = 0.86$.

Figure 2 shows the behavioural and histological results from one animal. IHCs were present throughout the cochlea and the OHCs disappeared between 11 and 13 mm from the apex. At the higher frequencies, the threshold shift ranged from 42 to 52 dB. In the five animals surviving drug treatment, thresholds were measured at 21 shifted frequencies which were well above the transition region. The amount of shift ranged from 30.2 to 52.3 dB (mean 39.9 dB).

To ensure that the high frequency shifted thresholds appropriately reflected the response of IHCs alone, it was necessary to show that the high frequency responses were not somehow produced by the low frequency, undamaged portion of the cochlea. A masking experiment was therefore performed. White noise, low-pass filtered with a rolloff of 84 dB per octave at 3 kHz, was introduced continuously into the test environment. A noise level was chosen such that thresholds at 3 kHz and all lower frequencies were increased by about 40 dB. Figure 2b shows that the high frequency thresholds were not affected, clearly indicating that they were produced in the unmasked region of the cochlea and thus they truly reflect the sensitivity of the IHCs in the absence of OHCs. CM rolloff matched the behaviourally measured loss of sensitivity in all animals for which it was measured.

Our interpretation of these data depends on two major assumptions. First, we assume that the IHCs that appeared intact under the phase contrast microscope were functionally

Fig. 1 a, Distribution of OHCs present in six animals, all three rows combined. Region counted is indicated by extent of the baseline. Top animal died during treatment. Ordinate, percentage of OHCs present at a given cochlear location; abscissa, distance along the basilar membrane, measured from the apical end. In all animals the IHC population (range 95-100%) was virtually intact. b, Threshold shift in the same six animals (hatching). Plots represent difference between ten audiograms obtained and averaged before and after drug treatment, except for the top animal. In the latter case, the audiogram obtained on the last day before death was used as the post-treatment measure.

Fig. 2 *a*, Distribution of hair cells present along the cochlea in one animal. Subscript indicates row of OHCs. Hatching in the IHC plot, and gaps in the OHC baselines, represent a region of the cochlea which cannot be counted. *b*, Threshold shift measured after kanamycin treatment (●). Threshold shift measured after kanamycin treatment with low-pass (<3 kHz) masking noise present (○).

normal¹⁴. (Subtle morphological changes in hair cells, appearing normal when examined under the light microscope, may be observed with the electron microscope¹⁴.) Whether such changes influence hair cell function is open to speculation. Our working hypothesis is that subtle changes in cytoarchitecture would not significantly impair the transducer properties of the cell. While this cannot be directly confirmed, the fact that behavioural thresholds were completely normal at all frequencies below the region of threshold shift provides a basis for making this assumption. Secondly, we are assuming that the observed threshold changes are directly related to hair cell losses; that is, we assume that the drug treatment did not affect neurones of the afferent VIIIth nerve. Given the good agreement between the behavioural, physiological and histological data, this seems reasonable.

These data have several, potentially important implications. Firstly, it is apparent that in direct contrast with many studies using intense sound to create hair cell damage¹⁵⁻¹⁸, kanamycin ototoxicity yields such cochlear lesions that histological and audiometric measures are well correlated. In other words, with the well defined damage patterns observed, there is no sign of anomalous findings such as normal threshold in the presence of significant hair cell loss, or threshold shift in the absence of hair cell loss. Our data clearly show that in the chinchilla, just as in the guinea pig^{9,10}, kanamycin poisoning induces a selective OHC loss that progresses from base to apex. This permits the fashioning of cochleae in which the basal half is completely denuded of OHCs without significant IHC loss. Clearly, when one wishes to study IHC function, either with behavioural or physiological means, preparations of this type are greatly preferable to those where mixed hair cell losses tend to occur, resulting in a patchy damage pattern.

It seems therefore that the loss of OHCs has a well defined effect on auditory sensitivity. Audiometric thresholds are

about 40 dB poorer at frequencies where OHCs are absent from the corresponding cochlear location. This shift in sensitivity is extremely well correlated with the finding that the threshold change of the whole nerve action potential (AP) in guinea pigs having similar cochlear lesions is also of the order of 40 dB (ref. 5). We have also noted previously that the difference in cochlear microphonic production between OHCs and IHCs is between 30 and 40 dB (ref. 5). Thus a good three-way correlation among the various indices of cochlear function can be seen, all indicating that OHCs are the primary determinants of low intensity auditory behaviour, or at least of sensitivity. These findings are of considerable theoretical importance when one considers Spoendlin's¹⁹ demonstration that about 95% of the afferent auditory nerve fibres innervate the inner hair cells, and when the apparent homogeneity of response characteristics of auditory nerve fibres²⁰ is also taken into account. It seems probable that there is interaction between the outputs of OHCs and IHCs, either synaptic or ephaptic. Although there is considerable controversy over the existence of sufficiently close apposition (or synaptic contacts) between outer and inner hair cell dendrites to permit significant interaction^{1,21}, the experimental results seem to suggest such. These interactions do not appear to be of such nature that OHCs would inhibit IHC output as has been suggested⁸. Instead, the most parsimonious assumption is that the OHCs are specialised to perform a facilitatory function on the IHCs. The homogeneity of neural recordings suggest that all such data are probably obtained from a single population, most likely from the more numerous fibres which originate on IHCs. Behavioural and peripheral physiological data suggest that without OHCs the system is incapable of operating at low sound levels. These considerations lead to the conclusion that information processing is performed by the IHCs but that, at least at low intensities, they require facilitation by the more sensitive OHCs. Complex interactions between OHCs and IHCs have been suggested by several authors. We think that the interaction is probably not more complex than the above postulated facilitation. To demonstrate this, extensive behavioural data are necessary, collected in the absence of OHCs, on suprathreshold auditory properties and on frequency discrimination. Such data are now being obtained in our laboratory.

We thank W. Ballard, M. A. Cheatham, J. A. Ferraro and T. McGee for their contributions. Research was supported by grants from NINDS.

Enrichment of fungal mutants by selective cell-wall lysis

SEVERAL procedures for enrichment of fungal mutants are known and have been reviewed^{1,2} but they have many limitations. Here we describe a new technique based on selective cell-wall lysis, which has wide applicability and is highly efficient for isolating mutants differing from the wild-type strain in growth requirements.

From the time of the early basic publications³⁻⁷, emphasis has been put on the importance of the physiological age of cells as regards protoplast formation by wall-lytic enzymes. Young cells are much more apt to yield protoplasts than are old ones.

Our method makes use of this fact and conditions are employed in which only the parental cells and not the desired mutants, can grow. The parental cells then become physiologically 'young' and sensitive to wall-degrading enzymes, whilst the mutants remain resistant, and can therefore be selected.

If the enzyme treatment is carried out in an osmotically-stabilised medium, the sensitive cells give rise to protoplasts which may be lysed by diluting the medium. This selective killing may also be achieved directly by using an environment not stabilised osmotically. The required mutants can then be isolated on selective media.

Here we report results obtained primarily with *Schizosaccharomyces pombe* wild-type strain L972 *h*⁻, with the adenine-requiring strain⁸ M210 *ade6 h*⁻, and with a number of auxotrophic and temperature-sensitive mutants of the wild-type strain. If not otherwise stated, cells were cultivated in liquid minimal medium containing vitamins⁷ at pH 5.5 with or without additional nutrients. The cell wall was degraded with a sterile-filtered, freeze-dried preparation of the digestive juice of the snail *Helix pomatia*. A 2% (w/v) solution of the digestive juice was prepared in this culture medium, without the use of an osmotic stabiliser. Enzyme treatment was performed with shaking at 25°C and a cell concentration of 10⁵ ml⁻¹.

To establish the optimum treatment time, suspensions in minimal medium were prepared from young and 1-week old cells of the wild-type strain. Snail enzyme preparation was added to the cells and samples were taken at intervals. Through the action of the enzyme preparation the young cells began to yield protoplasts, which immediately underwent lysis in the unstabilised medium. The rate of cell-wall degradation was followed indirectly by determination of the number of surviving cells. The data are plotted in Fig. 1a. After about 3 h practically all of the young cells had been killed, whereas the number of old cells had barely changed. On longer treatment, however, the cell-wall degradation of these also became apparent.

The behaviour of young and old adenine-requiring cells agreed with that of corresponding wild-type cells.

In the model enrichment experiments we used the wild-type strain and also the adenine-requiring mutant, which forms

Fig. 1 Effects of enzyme treatment on *Schizosaccharomyces pombe* cells. a, Surviving cells of wild-type young (●) and old (○) cultures; b, surviving cells of wild-type (■) and adenine-requiring (□) cultures after 6 h incubation in minimal medium and 6 h enzyme treatment. Arrows indicate the addition of snail enzyme. Bars represent standard errors.

red colonies on media of low adenine content. As the colonies of the wild-type strain are white, the two types of colony can easily be distinguished. For better approximation to reality, a 100:1 mixture of wild-type and auxotrophic cells from 4-d-old colonies was used. The enzyme treatment was begun after an incubation of 6 h in minimal medium allowing exponential growth for the wild-type strain but not for the auxotrophic mutant. Figure 1b shows that after a 6 h enzyme treatment the wild-type cells were nearly all killed, while the majority of the mutant cells remained.

The efficiency of selective cell-wall lysis was enhanced markedly with the use of 2-deoxyglucose, an inhibitor of cell-wall synthesis⁹⁻¹¹. Work involving 2-deoxyglucose will be reported elsewhere. The following experiments, aimed at the isolation of new mutants, took place without 2-deoxyglucose.

In the actual enrichment process, cells of the wild-type strain, spread on the surface of yeast-extract-glucose agar medium, were subjected to ultraviolet irradiation from a Philips TUV 15 W lamp (450 erg mm⁻²; 1% survival). After subsequent incubation for 4 d, during which the mutations were manifested and the cells became old as regards cell-wall lysis, the colonies formed from the surviving cells were washed off, diluted to 10⁵ cells ml⁻¹ with minimal medium and incubated for 6 h at 25°C. This was followed by enzyme treatment for 6 h. Samples were taken before and at the end of the enzyme treatment. The samples were spread on yeast-extract-glucose agar medium, incubated for 2 d, and the colonies appearing were then replicated on to minimal medium. The mutants were isolated and their requirements determined. The degree of enrichment was found by comparison of samples taken before and after enzyme treatment.

The average values are based on data obtained with 18 different mutants, with which the ratios could be calculated exactly. In these cases the average proportion of mutants in non-enriched samples was 0.57±0.07%. The enrichment calculated on the basis of the average of the individual enrichments was 79.7-fold (*s*_x = ±14.4). No correlation could be found between the type of auxotrophic mutant and the proportion of enrichment. In many experiments it was not possible to establish the exact value of the enrichment, for the mutant could not be detected in samples which were not enriched.

Temperature-sensitive mutants from the wild-type strain have also been isolated by using ultraviolet irradiation and the enrichment procedure described above. Those mutants were isolated which could readily grow at 25°C, but for which 35°C was non-permissive. In this case an average enrichment of 80.5-fold ($s_x = \pm 17.2$) was obtained, higher even than for the nutritionally-deficient mutants.

The results can be still further improved, with correspondingly good efficiency, by repetition of the enrichment procedure.

Selective cell-wall lysis similar to that described here for *Schiz pombe* was also attained with snail enzyme or enzymes of microbial origin for *Saccharomyces cerevisiae*, *Candida albicans*, *Geotrichum candidum*, *Rhodotorula mucilaginosa* and *Aspergillus nidulans*. Frequently, however, supplementary procedures were also necessary to achieve efficient cell-wall degradation. For *S. cerevisiae*, *C. albicans* and *G. candidum* the effect of snail enzyme was optimum in the presence of 0.1% 2-mercaptoethanol. Selective lysis could be induced in all cases with cell-wall degrading enzymes of certain *Streptomyces* and *Actinomyces*. The details will be reported elsewhere.

Protoplasts have already been produced from cells of a large number of fungal species by means of snail digestive juice or enzymes of microorganisms. Thus, the proposed enrichment method based on selective cell-wall degradation may be widely applicable to fungal mutants differing from the wild-type strain in growth requirements, and possibly to mutant cells of higher plants in cell culture.

We thank Dr H. Gutz for strains of *Schiz pombe*, Dr D. H. Williamson and Dr O. M. H. de Vries for valuable discussions.

Activity of vitamin A analogues in cell cultures of mouse epidermis and organ cultures of hamster trachea

FIFTY years after the discovery that vitamin A controls cell differentiation in epithelial tissues the mechanism involved is still unknown. The recent introduction of two-cell and organ culture systems, involving serum-free medium, for the assay of vitamin A activity *in vitro* may help. One assay uses epidermal cell cultures derived from mouse skin¹ and the other uses tracheal organ cultures from vitamin A-deficient hamsters². In both, the observed cellular response depends on the addition of vitamin A, which induces a marked increase in the cellular RNA of the skin cultures and a change from the production

of keratin to the production of cilia and mucus in the tracheal organ cultures. We have now investigated the biological activity of seven analogues of natural vitamin A ester (β -retinyl acetate) and vitamin A acid (β -retinoic acid), in line with the common practice of assaying physiological and pharmacological actions of vitamins, hormones and drugs using structural analogues of a parent compound. In the analogues we used, the 5,6-cyclohexenyl ring system of natural vitamin A is modified substantially. Although data obtained *in vivo* show that modification of the ring portion of the molecule can reduce growth-promoting activity³⁻⁵, we found that several vitamin A analogues with alterations in the ring, including a shift of the 5,6-double bond of the cyclohexene ring to the 4,5-position and replacement of the cyclohexene ring with substituted aromatic and cyclopentene rings, have substantial activity in the skin and tracheobronchial assays. Because of the sensitivity of the two assays it is now possible to assay vitamin A activity in the 10^{-8} – 10^{-10} M range (30–300 pg ml⁻¹). Moreover, there is excellent correlation between the results of the two assays in terms of the evaluation of biological activity of new analogues.

Vitamin A analogues (Fig. 1) were dissolved in dimethylsulphoxide (DMSO) and stored in a liquid nitrogen refrigerator. Growth and evaluation of epidermal cell cultures¹ and tracheal organ cultures² have been described in detail. The medium for epidermal cell culture was CMRL-1066 (ref. 6), containing 0.5% crystalline bovine albumin, 2 mM glutamine, penicillin (100 U ml⁻¹), and streptomycin (100 μ g ml⁻¹), for tracheal organ culture the medium was CMRL-1066, containing crystalline bovine insulin (1.0 μ g ml⁻¹), hydrocortisone hemisuccinate (0.1 μ g ml⁻¹), and glutamine, penicillin and streptomycin as above. The final DMSO concentration in epidermal cell cultures and tracheal organ cultures did not exceed 1.0% and 0.3%, respectively, all control cultures were treated with an equivalent amount of DMSO.

The effects of each vitamin A compound on RNA, DNA and protein content of epidermal cell cultures are shown in Table 1, their activity in reversing keratinised squamous metaplasia in tracheal organ culture is shown in Table 2. Data are reported for 230 cell cultures and 563 organ cultures. There is a good concordance in the results obtained in the two assay systems. Figures 2 and 3 show the type of dose-response profile that can be obtained in the epidermal cell culture assay. It is readily apparent that the 5,6-cyclohexenyl ring of naturally occurring vitamin A can be replaced with other structures without substantial loss of activity in the two assays. However, none of the synthetic analogues used had significantly greater activity than β -retinoic acid. Two analogues,

Fig. 1 Structures of β -retinoic acid and its analogues with modifications of the ring. In the analogues, the portion of the β -retinoic acid molecule shown in dotted brackets has been replaced with the structures shown.

Epidermal cells were grown for 3 d with the above vitamin A analogues. Values are expressed as the percentage increase in RNA, DNA or protein in the cultures, compared with control cultures which received no vitamin A. The mean values for such control cultures, after 3 d of growth, were as follows: total RNA per dish, 5.8 μ g, total DNA per dish, 9.3 μ g, and total protein per dish, 196 μ g. At the start of the experiment (zero-time controls), these mean values were: RNA, 5.8 μ g per dish, DNA, 7.2 μ g per dish, protein, 82.3 μ g per dish.

the furyl and pyridyl derivatives of retinoic acid, seemed to be almost devoid of activity, while the phenyl analogue had only minimal activity. There is no obligatory requirement for a 5,6-double bond in the cyclohexene ring, since both α -retinoic acid and α -retinyl acetate had marked activity in both assay systems. Similarly, both the dimethylacetylcyclopentenyl

**Fig 2** Dose-response curves, showing effects of both active and inactive vitamin A analogues on RNA content of mouse epidermal cell cultures. Structures of analogues are shown in Fig 1. ●, β -Retinoic acid, □, DACP, ▲, phenyl, ○, pyridyl.

(DACP) and trimethyl-methoxyphenyl (TMMP) analogues, in which the ring system has been even more substantially altered, also had marked activity in both assay systems. It is interesting that the DACP analogue of retinoic acid has been reported to block the hyperplastic and metaplastic effects of 3-methylcholanthrene on prostatic epithelium⁷, while the ethyl ester of the TMMP analogue of retinoic acid prevents skin carcinomas and papillomas in mice after exposure to polycyclic hydrocarbons⁸.

The results shown in Table 1 and Fig 2 suggest that the action of vitamin A in the differentiation of epithelial tissues involves an effect on RNA metabolism, we have reported⁹ an abnormal electrophoretic pattern of the high molecular weight RNA molecules synthesised in tracheal epithelium of vitamin A-deficient hamsters. Effects of vitamin A in stimulating nucleoside incorporation into RNA in other tissues have also been reported^{10,12}, but in each case the molecular site of action is unclear.

**Fig 3** Dose-response curves, showing effects of both active and inactive vitamin A analogues on DNA content of mouse epidermal cell cultures. Structures of analogues are shown in Fig 1. Symbols as in Fig 2.

All tracheas were cultured for the first 4-6 d in medium without vitamin A. At this time, some tracheas were collected, while the rest were cultured for a further week in medium containing either no vitamin A or added vitamin A or vitamin A analogue. These tracheas were collected on the days 11-13 of culture. Cultures were graded as to the percentage of their total epithelium showing squamous metaplasia on eight cross sections from the middle of each trachea. If more than 40% of the total epithelial length was squamous, it was graded as having severe squamous metaplasia, between 10-40% was graded as marked, between 2-10% was graded as mild, and less than 2% was graded as minimal.

Obviously the *in vitro* systems for assay of vitamin A analogues do not necessarily give an evaluation of activity identical to that obtained with earlier tests of growth promotion in the whole animal. It has long been known that there may be a dissociation between the ability of a vitamin A analogue to support growth in the whole animal and to maintain specific epithelial structures, as in the case of β -retinoic acid and testicular epithelium^{13,14}. More recently, it has been shown¹⁵ that the DACP analogue of retinoic acid will not support growth in the rat, and yet we have found that this compound has definite vitamin A activity in both the epidermal and tracheal culture assays. Thus it seems that as new, more specific *in vitro* assay systems become available, the generic concept of vitamin A activity is becoming obsolete. It is increasingly essential to define the vitamin A activity of a specific chemical structure in terms of a specific biological or biochemical function, much in the same way as this was necessary some time ago for the understanding of structure-function relationships of adrenocortical steroids. The striking concordance of measured activity of vitamin A analogues in our two culture systems suggests that both systems measure a similar fundamental biological or biochemical property of related molecules.

We thank William Henderson for feeding of vitamin A-deficient diets, and Doris Overman for help in preparation of

the manuscript. Vitamin A analogues were provided by Hoffmann-La Roche Inc, insulin by Eli Lilly and Co, and hydrocortisone hemisuccinate by The Upjohn Company.

Thyroid hormone conformation from NMR studies of triiodothyropropionic acid

We have measured NMR spectra of triiodothyropropionic acid, a thyro-active analogue of the thyroid hormone triiodothyronine, to obtain information about the effects of differing solvent environments on hormone conformation

3,5,3'-Triiodo-L-thyronine (T_3) is the most potent naturally occurring thyroid hormone, and its conformational characteristics have been much studied. The steric effects of the iodine atoms favour a conformation with the iodinated phenyl rings lying in approximately mutually-perpendicular planes, and the 120° angle at the ether oxygen produces conformational distinction between the chemically identical 3' and 5' positions on the β ring. Thus the 3'-iodine of T_3 may be positioned either proximal or distal to the α ring (Fig 1). Although rotation of the β ring is possible, Jorgensen *et al*^{1,2} concluded from biological testing of conformationally fixed analogues of T_3 that the 3'-iodine distal arrangement is the important one at the hormonal receptors

An X-ray crystallographic determination of the three-dimensional structure of hydrated T_3 hydrochloride³ showed it to have the opposite conformation, that is the 3'-iodine is proximal to the α ring. Structure determinations of thyromimetic T_3 analogues, 3,5,3'-triiodothyropropionic acid ethyl ester⁴ and hydrated 3'-isopropyl-3,5'-diiodo-L-thyronine hydrochloride⁵ were performed and revealed both of these molecules also to have crystallised with conformations in which the 3'-substituent is situated in the proximal position. Subsequently, conformations with the β ring oriented with the 3'-iodine in the distal position were discovered in the crystal structure determinations of T_3 (ref 6), 3,5,3'-triiodothyroacetic acid-N-diethanolamine⁷ and T_3 methyl ester⁷

These results raise questions regarding the relative stabilities of the proximal and distal conformations, both in solid state and in solution, and the conditions under which each is favoured, and why. The crystals in which the 3'-substituent proximal positioning occurs were all obtained from acidic (HCl) solutions while the distal-conformation crystals were from alcohol with excesses of organic reagents often present. It seems therefore that the crystallisation medium plays a crucial role in promoting crystallisation of only one conformation or the other. Since crystallisation must be preceded by a local ordering in solution, it seemed likely to us that differences in the equilibrium populations of the proximal and distal conformers would exist in the different crystallisation solutions, and that these differences might be detectable using nuclear magnetic resonance (NMR) spectroscopy

We chose 3,5,3'-triiodothyropropionic acid (T_3P) as a representative T_3 structural analogue for the NMR spectral study in different solutions. The solutions were chosen to duplicate as closely as possible the conditions under which proximal and distal conformations of thyromimetics were crystallised, and consisted of (i) T_3P (~ 0.08 M) in a 2:1 mixture of ethanol-1N HCl, the medium from which proximal

triiodothyropropionate crystallised⁴, and (ii) T_3P (~ 0.06 M), diethanolamine (~ 0.06 M), and urea (~ 0.6 M) in methanol, the relative conditions under which distal triiodothyroacetic acid-N-diethanolamine was obtained⁷. The molar concentration of T_3P used was the maximum that could be obtained under the given conditions. The spectra were recorded at room temperature on a 220 MHz spectrometer, with tetramethylsilane as an internal reference

Figure 2 shows the NMR spectra of the aromatic-ring protons of T_3P in the two solutions. Peak assignments are labelled on the figure, and the chemical shifts are given in Table 1. The spectrum of T_3P in methanol-urea-diethanolamine is indicative of either only one species being present, or, possibly, a time-averaged distribution of species whose inter-conversion time (by β ring rotation) is very fast. The spectrum of T_3P in acidic ethanol, however, shows doubling of all the proton peaks, and is consistent with an interpretation of two distinct species being present, with a major:minor species ratio of about 3:1. The peaks due to the 2'-hydrogen of the major

Table 1 Chemical shifts p.p.m. of aromatic ring hydrogen atoms in T_3P NMR spectra

Atoms	CH ₃ OH-diethanolamine	CH ₃ CH ₂ OH-HCl	
	urea	Major peaks	Minor peaks
H _{6'}	6.57	6.560	6.544
H _{5'}	6.76	6.816	6.810
H _{2'}	7.01	7.000	7.028
H _{2,6}	7.81	7.760	7.775

species are displaced upfield from those of the minor component while the 5'- and 6'-proton peaks of the major species are downfield from the corresponding peaks of the minor entity, this is what would be expected if the 2'-proton of the major species were closer to the α ring and the 5'- and 6'-protons farther from the α ring than the corresponding atoms in the minor species. Thus the major entity is indicated to be the 3'-iodine proximal conformation, and the minor species the distal one. (Even the relative amounts of the displacements of the corresponding peaks of the two species agree with the relative distances of the protons from the α ring in each case.)

We also recorded a higher temperature NMR spectrum of T_3P in ethanol-HCl to observe the stabilities of the species present. No significant coalescence of the peaks occurred at approximately 60° C.

The above interpretation is consistent with and substantially clarifies the crystallographic results. In acidic (HCl) solutions the 3'-substituent proximal conformation predominates, and that is the conformation which crystallises from such media, in the other medium, from which the distal conformation crystals were obtained, only a single-species spectrum is obtained. If this represents a time-averaged distribution presumably the distal conformation is favoured (or perhaps just less soluble), but if so, the energy difference is too small for both species to be isolated by NMR at room temperature. The NMR results also pose some problems: for example (i) why does acidification of the medium cause the stabilisation of the 3'-iodine proximal arrangement, and (ii) why is the energy barrier for interconversion of the species in acidic media so high—the non-coalescence

Fig 1 Proximal and distal conformations of asymmetric β ring thyromimetics

of the splittings at 60° C implies a free energy of activation of at least 20 kcalorie mol⁻¹ (calculated from the 5'-hydrogen peaks separation). These questions and others pertaining to the effects of differing milieus on conformational stability are being investigated in our laboratories by systematic NMR studies at controlled pH and temperatures.

We thank Dr A. A. Grey and the Ontario Research Foundation for recording the NMR spectra. Support was from the Medical Research Council of Canada and the National Institutes of Health. A. C. is the recipient of a research career development award from the National Institute of Neurological Diseases and Stroke.

Increased axoplasmic flow associated with pargyline under conditions which induce a myopathy

The suggestion that an abnormality of the circulation might be important in the pathogenesis of Duchenne muscular dystrophy¹⁻³ has been supported by the abnormal intrafibrillar fluorescence of muscle biopsies⁴, which is presumed to be due to the presence of catecholamines⁵. Accumulation of cate-

cholamines, accompanied by the appearance of a myopathy, can be induced by the monoamine oxidase inhibitor pargyline⁶, while this myopathy can be prevented by sectioning of the sciatic nerve. This suggests that the induced myopathy is dependent on an intact nerve supply to the muscle and that catecholamines are involved in the process. Studying fast axoplasmic flow in rats treated with pargyline, we have obtained evidence of altered nerve function.

Male Sprague-Dawley rats (150-170 g) were given daily intraperitoneal injections of pargyline. The drug solution was prepared each day by dissolving 20 mg ml⁻¹ of normal saline and injecting 75 mg kg⁻¹ body weight⁵. Fast axoplasmic flow was studied in rats anaesthetised with pentobarbital (50 mg kg⁻¹) by injecting ³H-L-leucine (44.2 Ci mmol⁻¹, New England Nuclear Corp.) into the right ventral horn of the exposed spinal cord at spinal levels L-5 and L-6 as described by Lasek⁶. The animals were killed after 0.5-2.5 h, and the sciatic nerve and the L-5 and L-6 spinal roots were dissected out intact, cleaned of connective tissue and frozen immediately on a steel ruler using a Cryoquick spray. The frozen nerve was cut into 3-mm segments which were dissolved in 1 ml of Soluene 350 (Packard), 10 ml PCS (Amersham/Searle) was added and the samples were counted.

Examples of the distribution of radioactivity expressed as d.p.m. per 3-mm nerve segment as a function of the distance along the sciatic nerve are shown in Fig. 1. In the rat given saline as a control, a labelled front migrated 40 mm in 2.5 h, while 24 h after a single dose of pargyline the radioactive front extended to 35 mm within the first 1.5 h. Furthermore, as the number of doses of pargyline increased, the rate of transport of ³H increased to 52 mm h⁻¹ for rats exposed to pargyline for 3 d and 46 mm 0.5 h⁻¹ for those exposed for 7 d. For both groups the flow of material down the nerve appears to have separated into multiple fronts. This might be due to drug-induced alterations in the rate of migration of different populations of ³H-containing molecules, that is proteins and glycoproteins, both being transported by fast axoplasmic flow⁷. Slow axoplasmic

Fig. 1 Distribution of protein-bound radioactivity along the sciatic nerve of NaCl control (a) and 1 (b), 3 (c) and 7 d (d) pargyline-treated rats. Animals were killed at 2.5 h (a), 1.5 h (b), 10 h (c) and 0.5 h (d) respectively after labelling the spinal cord with ³H-leucine.

Table 1 Pargyline-induced increase in fast axoplasmic transport of ^3H -labelled material in the rat sciatic nerve

Pargyline 75 mg kg ⁻¹			Pargyline 25 mg kg ⁻¹		NaCl control
1 d	3 d	7 d	3 d	7 d	7 d
552±9 n = 4	1,262±117 n = 7	1,996±270 n = 8	877±45 n = 3	1,428±35 n = 4	390±13 n = 5

Figures are mm 24 h⁻¹±s.d

flow⁸ does not appear to play a role in the development of this myopathy because the rate of slow flow is 1–2 mm d⁻¹ and necrosis is evident already after the first day of pargyline administration⁵

The rate of migration of ^3H down the nerve was related to the number of days the rats were exposed to pargyline increasing from 1 to 7 d, and was affected by the dose received each day (Table 1). The response elicited by pargyline could be duplicated by another monoamine oxidase inhibitor phenelzine (40 mg kg⁻¹) suggesting that an increase in monoamine levels was involved in the increase in the rate of axoplasmic flow. This was supported by our observation that pretreatment with α -methyl paratyrosine (200 mg kg⁻¹) decreases by 30% the increase in rate of fast axoplasmic flow induced by pargyline given for 3 d.

An abnormally large amount of catecholamines excreted in the urine⁹ and present in muscle⁴ of genetically dystrophic patients has been documented. In addition a model has been presented³ suggesting that a vascular abnormality with an increased sensitivity to the level of catecholamines is responsible for the development of an experimental myopathy similar to that found in Duchenne dystrophy. Monoamines are important inhibitory mediators in the central nervous system^{10,11}, and in patients with Duchenne dystrophy fewer than the usual number of functional motor units have been reported¹². We suggest that a rise in monoamine levels induced by monoamine oxidase inhibitors activates the inhibitory response in the central nervous system leading to depression of motor neurones in the spinal cord and therefore a decrease in the level of muscle activity. This could lead to an increased demand by the muscle for trophic factors which would in turn increase the rate of axoplasmic flow. A similar mechanism could explain some of the findings reported for Duchenne muscular dystrophy.

We thank the Canadian Muscular Dystrophy Association for financial support and Dr K. Jhamandas for helpful discussions.

New pathway for metabolism of dopa

L-DOPA (3, 4-dihydroxyphenylalanine) has, since 1967, been used in large doses clinically to lessen the degree of akinesia, rigidity and tremor in Parkinson's disease¹. The impetus for dopa therapy came from the discovery of abnormally small concentrations of dopamine in the basal ganglia of patients with Parkinsonism². Since catecholamines cannot cross the blood-brain barrier, dopa, the immediate metabolic precursor of dopamine, became the logical candidate for clinical trials. Administration of dopa increases dopamine in the basal ganglia³, and this is believed to be the primary mode of action of the drug. Although partially correct, this cannot account for the so-called on-off effect⁴—the increase in therapeutic benefits derived from prolonged use of dopa⁵—and side effects such as nausea, vomiting and personality disturbances. The latter are minimised by simultaneous administration of decarboxylase inhibitors which limit peripheral decarboxylation and allow smaller doses of dopa to be effective. Nonetheless it seems that the action of dopa is complex, with several mechanisms operative. It is therefore important to elucidate all possible metabolic fates of dopa and consider their relationship to the various effects of dopa. We report here *in vitro* evidence for a minor pathway of dopa metabolism resulting in the formation of 3,4-dihydroxyphenylacetaldehyde (DHPA) with concomitant inactivation of dopa decarboxylase.

α -Methyldopa, a poor substrate of dopa decarboxylase, inactivates this pyridoxal 5'-phosphate (PLP)-dependent enzyme⁷ as a result of abortive transamination⁸, a side reaction producing apoenzyme, pyridoxamine 5'-phosphate (PMP) and the aldehyde or ketone (in this case, 3,4-dihydroxyphenylacetone) derived from decarboxylation and transamination of the substrate. First observed in the decarboxylation of α -methylglutamate by glutamate decarboxylase⁹, abortive transamination was found to occur to a lesser degree with glutamate itself¹⁰. Mechanistically, transamination follows decarboxylation if protonation of the enzyme-bound Schiff's base occurs at C₄ instead of C _{α} (Fig. 1).

Fig. 1 Protonation of the enzyme-bound Schiff's base at C₄ and C _{α}

Hydrolysis of the Schiff's base then yields an aldehyde or ketone and PMP, which dissociates, leaving apoenzyme. Abortive transamination may be a general reaction of PLP-dependent decarboxylases with all substrates. Because several grams of dopa per day must be metabolised by patients on dopa therapy, even a small fraction of the turnover resulting in production of DHPA and inactivation of dopa decarboxylase could be

Table 1 Ratio of radioactivity added to that isolated

Experiment	c p m added as ^3H -dopa	c p m isolated as 2,4-dinitrophenylhydrazone	% Transamination
1	4.7×10^7	4.1×10^4	0.009
2	4.9×10^7	6.7×10^4	0.014
3	4.6×10^7	6.2×10^4	0.013
4	4.9×10^7	6.0×10^4	0.012
			Average 0.012

Dopa decarboxylase was purified partially from hog kidney homogenate to a specific activity of 1,000 U mg^{-1} (1 U = 1 nmol CO_2 produced per min) using a procedure combining aspects of published protocols^{11,12}. In a typical experiment to detect DHPA, the enzyme was incubated in 5.0 ml 0.1 M phosphate buffer, pH 7.0, containing 10^{-4} M PLP, 2 mg ^3H -dopa, synthesised¹³ by acid-catalysed exchange of aromatic protons with T_2O , in 0.4 ml buffer was added, and the reaction proceeded for 5 min. Sufficient enzyme was present to decarboxylate >90% of the substrate in this time. After addition of a small amount of unlabelled DHPA¹⁴ as a carrier, the solution was extracted with two 5-ml portions of ethyl acetate. The combined extracts were dried over Na_2SO_4 and were concentrated to approximately 50 μl with a rotary evaporator. This solution was applied to the corner of a 10×10 cm silica gel thin layer chromatography plate and was chromatographed with ethyl acetate. An ethanolic solution of 2,4-dinitrophenylhydrazine was sprayed on the spot corresponding to DHPA ($R_F = 0.54$), and a second chromatography, using ether as a solvent, was done at right angles to the original direction of elution. The orange spot ($R_F = 0.46$) corresponding to the 2,4-dinitrophenylhydrazone of DHPA was scraped from the plate and counted.

physiologically significant. We therefore investigated whether dopa decarboxylase catalyses this abortive transamination of dopa.

The detection of DHPA as a by-product of the enzymatic decarboxylation of dopa is described in the legend of Table 1. We used ^3H -dopa of high specific activity (0.1 mCi mg^{-1}) and isolated the somewhat unstable aldehyde as its 2,4-dinitrophenylhydrazone, which contained significant amounts of label. Table 1 compares the c p m found in the derivative with the c p m added initially as ^3H -dopa. The ratio indicates that approximately one in every 10^4 decarboxylations also results in transamination. Because of facile oxidation of the aldehyde and the semi-quantitative nature of the isolation of the phenylhydrazone, this represents a minimum value. If less enzyme was used, the radioactivity isolated was proportional to the amount of enzyme. When this experiment was done without enzyme or with heat-inactivated enzyme, less than 10% as much radioactivity was found in the phenylhydrazone. With a large excess of enzyme there was no additional radioactivity, eliminating the possibility that a trace amount of monoamine oxidase was responsible for production of DHPA.

In the absence of free PLP, dopa decarboxylase is inactivated by the abortive transamination. Enzyme freed of unbound PLP by gel filtration was incubated with 2×10^{-3} M dopa for various times. Remaining decarboxylase activity was determined by addition of 1.0 μmol of $1\text{-}^{14}\text{C}$ -dopa and collection of $^{14}\text{CO}_2$ evolved during the next 5 min. Inactivation by dopa occurred with $t_{1/2}$ of 6.6 min, comparable with the 2 min found for α -methyl-dopa⁸.

Addition of PLP to these partially inactivated solutions of enzyme showed that 30–50% reactivation was possible. The remainder of the original activity was lost, presumably because of the instability of the apoenzyme. There was no loss of activity when the enzyme was incubated at 37°C for 30 min in the absence of both free PLP and substrate.

The percentage of catalytic events leading to transamination can be calculated independently from the rate of inactivation. Assuming a maximum specific activity¹¹ of 9,000 U mg^{-1} , a molecular weight¹¹ of 112,000 and a $t_{1/2}$ for inactivation of 6.6 min, we calculate 0.01% for transamination against normal reaction—in agreement with the directly measured value.

The abortive transamination of dopa by dopa decarboxylase has been characterised by the demonstration of DHPA, inactivation of the enzyme in the absence of free PLP at a rate

commensurate with the amount of DHPA formed and the ability of PLP to reactivate the enzyme at least partially. The fractional turnover leading to transamination together with decarboxylation is small, but measurable.

Several questions can be asked concerning the importance *in vivo* of the abortive transamination of dopa. First, does DHPA arising from this pathway have physiologically significant effects which differ from those of DHPA formed by the oxidation of dopamine? Second, does the inactivation of dopa decarboxylase by this mechanism cause inhibition of dopa metabolism either peripherally or in the brain? Finally, if such inhibition indeed occurs, will the metabolism of other substrates of dopa decarboxylase be affected? The answers to these questions, when available, may aid in an understanding of dopa metabolism and Parkinsonism.

Histamine release by gastric stimulants

It is a matter of debate whether histamine in the gastric mucosa acts as a local chemical mediator for other gastric stimulants^{1–5}, and the isolated bullfrog mucosa provides a convenient model for investigation of the question. The preparation responds to gastric stimulants such as pentagastrin, acetylcholine and histamine, the secretory rate can be monitored easily and there are no complicating factors such as changes in blood flow. Nevertheless, conflicting reports have appeared. Davidson *et al.*⁶ found no changes in histamine content after addition of a gastrin-like pentapeptide, while Kasbekar *et al.*⁷ showed that pentagastrin and acetylcholine increased the efflux of labelled histamine. I have now used a more direct approach and found that histamine is released in response to pentagastrin and acetylcholine for which it seems to be a common mediator.

Isolated mucosa of *Rana catesbeiana* was mounted as a sheet between two sides of a leucite chamber. The serosal side had a capacity of 2.5 ml whereas the mucosal side could hold up to 4.5 ml. The normal serosal solution consisted of (mM) 89.4 NaCl, 3.0 KCl, 0.8 MgCl_2 , 18.0 NaHCO_3 , 1.8 CaCl_2 and 11.0 glucose. In the mucosal solution, glucose was omitted and NaHCO_3 was replaced by NaCl. Serosal solution was bubbled continuously with 95% O_2 /5% CO_2 and the mucosal solution

with 100% O₂. The area of the stomach exposed to the bathing solutions was 2.85 cm². The rate of secretion was monitored by a pH stat set at 7.7 as described earlier⁸. Freshly mounted stomachs secreted acid at rates varying from 6–10 $\mu\text{eq h}^{-1}$. With periodic changes of solutions, the rates of acid secretion declined during 8–12 h. Stomachs that secreted acid at rates of 2 $\mu\text{eq h}^{-1}$ or less, defined as 'resting', responded to exogenous stimulants added to the serosal solution⁹.

To estimate histamine in the serosal solution, the contents of the entire chamber were collected at various times. The starting or initial value was obtained on a sample collected in the first hour after dissection. After the stomachs had come to rest, a 30-min sample was collected ('control'). The serosal solution was then replaced with one containing one of the following stimulants: pentagastrin (5×10^{-6} M), acetylcholine (10^{-3} M) or dibutyl cyclic AMP (5 mM). These concentrations were used to obtain an optimal increase in acid secretion. Samples were collected at 15 or 30-min intervals. After each collection, the serosal side was refilled with the solution containing the same stimulant. Aliquots (1 ml) of the serosal solution were used to estimate histamine fluorometrically with an Aminco fluorophotometer¹⁰. The method depends on the production of a fluorophore by condensation of histamine with *o*-phthalaldehyde (*o*-PT). The fluorescent and activation spectra of the fluorophore obtained with the serosal solution and with standard histamine were indistinguishable. Appropriate blanks containing the stimulants were run concurrently, these usually gave negligible results except with solutions containing dibutyl cyclic AMP. The values of histamine obtained by these assays are expressed in terms of ng h⁻¹. This corrects for the different times of collection and also allows better correspondence with rates of acid secretion expressed as $\mu\text{eq h}^{-1}$. Freshly mounted stomachs secreted acid at a rate of $5.8 \pm 0.5 \mu\text{eq h}^{-1}$ ($n = 11$). The histamine liberated during that period was $498 \pm 78.8 \text{ ng h}^{-1}$. Resting stomachs secreted acid more slowly ($1.7 \pm 0.12 \mu\text{eq h}^{-1}$) and also had lower rates of histamine liberation ($135.5 \pm 12.6 \text{ ng h}^{-1}$).

Addition of pentagastrin or acetylcholine to the serosal solution led to a marked increase in the liberation of histamine and acid (Fig. 1), which reached a maximum and then declined. The release of histamine reached a peak in the first 15 min and then declined, and by the end of an hour it was near control values. In contrast, the rate of acid secretion was maximal after 25–30 min and even at the end of the hour it was significantly higher than the resting value. This suggests that the release of histamine

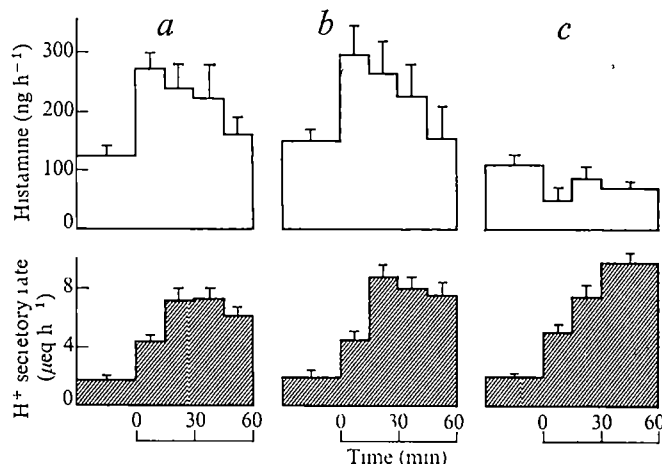

Fig. 1 Effects of adding (a) pentagastrin (5×10^{-6} M), (b) acetylcholine (10^{-3} M) or (c) dibutyl cyclic AMP (5 mM) to a resting frog stomach are shown. The drugs were added at time zero in each case. Samples were collected at 15 min intervals in the case of pentagastrin or acetylcholine. After each collection, the serosal side was refilled with the solution containing the same stimulant. The values shown are the means \pm s.e.m. for five experiments. Where dibutyl cyclic AMP was used (four experiments), two samples were collected at 15-min intervals and the third after 30 min.

Fig. 2 Increase in acid secretion on readdition of serosal (nutrient) solution to a resting stomach. A 90-min sample was collected early in the day (collect N) when the stomach was secreting spontaneously at a high rate. The sample was stored in the cold and added back after the stomach had come to rest (add N). Sixty minutes later, 10^{-4} M histamine was added to the serosal solution.

preceded the onset of acid secretion. Dibutyl cyclic AMP increased the rate of acid secretion but produced no significant increase in the release of histamine.

Figure 2 shows the results of an experiment in which a stomach was mounted as before, but after 30 min the serosal chamber was drained and 2.5 ml of fresh solution was added. After 90 min, the entire contents of that chamber were collected, labelled (N), and stored in the cold. After the stomach had come to rest, the serosal chamber was drained and refilled with the sample collected earlier, and allowed to warm to room temperature. As Fig. 2 shows, addition of the sample led to a marked increase in secretion of acid, which increased from $1.3 \pm 0.3 \mu\text{eq h}^{-1}$ to $3.8 \pm 0.7 \mu\text{eq h}^{-1}$ in four experiments. The stomachs also responded to exogenous histamine, 10^{-4} M. These experiments (a variation of the Loewi experiment on Vagustoff) show that the material that leaks out from the stomach into the serosal solution can stimulate acid secretion. The results of the first experiment suggest that the material is histamine.

The following conclusions can be drawn from this study. Histamine leaks from the frog gastric mucosa into the serosal solution in measurable amounts. The spontaneous secretion of the frog stomach mounted in chambers is due to histamine liberated either during pithing or dissection. The gradual decline in acid secretion presumably represents slow diffusion or metabolic degradation of the liberated histamine. The stores of histamine are not exhausted, however, and exposure to pentagastrin or acetylcholine leads to a transient release of histamine. The histamine that is released stimulates acid secretion, presumably by activating adenylcyclase¹¹. Dibutyl cyclic AMP acting at a stage beyond that of histamine release activates acid secretion directly. Thus histamine appears to be the common mediator for acetylcholine and pentagastrin in the frog stomach.

Dissociation of Factor VIII-related antigen into subunits

FACTOR VIII-related antigen is present in normal human blood plasma and with conventional separation procedures it is detected in the same fractions as Factor VIII, the active blood clotting factor. Its structure and absolute concentration in plasma are unknown but it is believed to be a protein of high molecular weight. Patients with von Willebrand's disease have antigen levels and Factor VIII levels reduced in approximately the same proportions while haemophiliacs have reduced amounts of Factor VIII but normal concentrations of antigen. A differential diagnosis between these two bleeding diatheses can therefore be made by measuring antigen level. It has been suggested that the reduced amounts of Factor VIII-related antigen in von Willebrand's patients may be responsible for some aspects of the bleeding encountered with this disease and also for some of the platelet abnormalities which are found.

It has already been shown that Factor VIII readily separates into subunits under the influence of concentrated saline solution^{1,2} or reducing agents^{3,4} and the antigen remains as a large intact molecule when the Factor VIII is dissociated. This illustrates a clear distinction between the two species and a method of separating them. Here we show that it is possible to dissociate Factor VIII-related antigen and that this dissociation may be detected using either immunoelectrophoresis techniques or the 'ristocetin aggregation test'.

Human Factor VIII used in these experiments was a concentrate made according to the method described by Newman *et al*⁵ for a material of intermediate potency. It was dissolved in 0.15 M saline to make a solution containing 10-20 units of Factor VIII activity ml⁻¹ (1 unit is defined as the amount present in 1 ml of average normal human plasma). When a sample of this starting material is subjected to gel filtration on Sepharose 4B the Factor VIII-related antigen appears in the first fraction, the so-called 'void volume'. Results of such an experiment are given in Fig 1 where antigen concentration is plotted against volume of eluate. The column dimensions were 260 mm × 15 mm and the chromatographic procedure was identical to that described previously⁴. Antigen is measured here as a percentage of the applied sample so that a total of all plotted values equals the overall recovery which in this case is 44%. Two methods of measurement were used, one was the immunoelectrophoretic method described by Zimmerman *et al*⁶ which is based on the Laurell technique⁷. The second method was the measurement of the effect on platelet aggregation by Ristocetin^{8,9}. It will be seen that both methods give the same results in terms of position and character of the eluted peak. Peak position is equivalent to 13.5 ml eluate which indicates a large molecular size probably greater than one million. Factor VIII itself gives a peak in the identical position⁴.

Factor VIII concentrate was reacted for 1 h at 37°C with 10⁻³ M dithiothreitol in 0.15 M saline. No buffers were

Fig. 1 Gel filtration of Factor VIII-related antigen before reaction. Antigen measured by immunoelectrophoresis (●) and ristocetin aggregate of platelets (×).

used but the solutions all had a pH between 6.5 and 7.0. After this incubation period the mixture was loaded on to a Sepharose 4B column, previously equilibrated with 10⁻³ M dithiothreitol in 0.15 M saline and the column was eluted with the same solution. In these conditions the elution pattern seen in Fig 2 was obtained. Now the antigen appears at a point equivalent to 26 ml of eluted volume indicating that the dithiothreitol treatment has dissociated it into subunits (total recovery = 40%). Comparison with previous work⁴ shows that this elution point is the same as that obtained for Factor VIII subunits and indicates that the molecular weight of the antigen subunit is identical to that of the Factor VIII subunit at least to within ± 25%. Calibration of the column using materials of known molecular weight showed that this elution peak position was equivalent to a molecular weight of 230,000. As with the intact molecule, results obtained using the two different methods of measurement were identical.

The level of dithiothreitol used to dissociate Factor VIII-related antigen in this work was 10⁻³ M as discussed earlier. At this concentration, Factor VIII clotting activity is destroyed, most of the destruction taking place in passage of the reaction mixture through the column (which is eluted with 10⁻³ M dithiothreitol). Factor VIII itself is dissociated at 1 × 10⁻⁴ to 3 × 10⁻⁴ M dithiothreitol⁴ for the samples in question and at this concentration the Factor VIII-related antigen remains intact as a large molecule. Thus there is a very clear difference between the antigen and Factor VIII even though it appears to be of degree. Unlike Factor VIII, it has not been possible to dissociate the antigen using high concentrations of sodium chloride but this is complicated by the fact that high saline concentrations precipitate proteins. Unlike Factor VIII it has not been possible to aggregate the antigen subunits using ε-aminocaproic acid.

There has been considerable discussion as to whether the two methods of measurement used in this work detect the same molecular species or not. As shown above these methods give identical results for the dissociated as well as for the undissociated antigen, so it must be concluded that they detect either the same or else very closely related species.

Dithiothreitol is a well known reducing agent, so it can be speculated that the subunits of Factor VIII-related anti-

Fig 2 Gel filtration of Factor VIII-related antigen after reaction with 10^{-3} M dithiothreitol. Antigen measured by immunoelectrophoresis (●) and ristocetin aggregation of platelets (x)

gen are joined by disulphide linkages and that these are severed by reduction in the dissociation process. A possible alternative, however, is that reduction of certain parts of the molecule have made the subunits less capable of fitting together. This possibility cannot be disregarded at the present time as such an explanation might be more acceptable in the case of Factor VIII itself when reactions other than reduction will cause dissociation.

It is becoming clear that there is an intriguing analogy between Factor VIII-related antigen and Factor VIII itself. The similarity in the size of subunits and the probable similarities in the intact molecule might suggest that they belong to the same class of compound. It could also be speculated that they each have the same number of subunits per molecule and this would be contrary to the hypothesis put forward that a single Factor VIII subunit is carried by the intact antigen. In spite of these similarities, however, there must be a distinct difference in the strength of cohesive forces binding the subunits to account for the fact that more strenuous conditions are required to dissociate the antigen. Thus, Factor VIII-related antigen and Factor VIII itself are not identical. M A H acknowledges the provision of a grant by the Medical Research Council.

Modulation excitation spectro-photometry of purple membrane of *Halobacterium halobium*

When *Halobacterium halobium* is grown at low oxygen concentrations in the light, it synthesises patches of membrane containing a purple pigment. If exposed to low salt concentrations, the cell membrane dissociates into fragments which differ in their protein and pigment composition and can be separated¹. The most conspicuous of these fragments is the so-called 'purple membrane'². The isolated purple membrane contains 25% lipid and 75% protein², only a single species of protein has been found. This protein, bacteriorhodopsin, is apparently similar to the animal visual pigment, it contains 1 mol of retinal per mol protein bound as a Schiff base to a lysine residue³. The protein forms a planar lattice in the membrane⁴ and shows a broad absorption maximum at 570 nm^{3,4}. Absorption of light converts the 570 nm species to a second species which absorbs maximally at 412 nm, and in the dark reconverts to the 570 nm complex within a few milliseconds. This is apparently accompanied by a conformational change in the protein, which cycles rapidly between the two conformations, releasing protons on one side of the membrane in the first transition and taking them up on the other in the second⁵. Thus, in the intact cells the bacteriorhodopsin seems to act as a light-driven proton pump^{6,7}.

The purple membrane has been the object of several spectrophotometric studies designed to elucidate the mechanism and kinetics of the photochemical reaction. These have usually been carried out by d.c. or flash methods and often at low temperatures or in solvents chosen to arrest the decay of the photo-transients^{5,8}. Using low-temperature spectroscopy, Lozier and Stoekenius have observed four spectrally distinct intermediates analogous to the rhodopsin, prelumirhodopsin, lumirhodopsin and metarhodopsin of invertebrates⁹. The two additional forms

Fig 1 Absorption spectra of transients in purple membrane suspensions in water (room temperature). Modulation frequency 5 Hz. Scales are in arbitrary units, true ratios between the peaks are -11 ± 23 for 410 nm/570 nm/660 nm. Excitation was by a 250 W high-pressure mercury arc with emission extending across the ultraviolet and visible regions. Similar results were obtained by excitation at 365 nm, using a standard filter. Purple membrane suspensions were prepared from *H. halobium* R₁ as described by Danon and Stoekenius⁷, the concentration of purple complex was 0.03 mM according to A measurements based on millimolar absorption coefficient of $63 \text{ mM}^{-1} \text{ cm}^{-1}$ at 568 nm⁵. Assuming a 1:1 correspondence between the bands at 410 nm and 570 nm, their molar absorption coefficients should be in the ratio 11:23. This compares well with the ratio 11:21 for the 415 nm and 568 nm peaks according to the data of Oesterhelt and Hess⁵.

of bacteriorhodopsin were observed to have absorption bands centred at 610 nm and 550 nm, with a maximum in the difference spectrum at 510 nm. Resonance Raman spectroscopy has indicated that a Schiff-base linkage may be directly involved in the proton translocation¹⁰. Here low-temperature and solvent trapping techniques were used to study the 412 nm complex.

Modulation excitation spectrophotometry offers a convenient way of studying systems of this kind under more natural circumstances. Moreover, the light intensities used are much lower than in the case of flash photolysis. The method has been described in detail^{11,12} and briefly consists of illuminating the sample with a modulated light while at the same time observing the modulation on a constant monitoring beam, thus allowing the absorption of phototransients to be obtained. The difference of phase between the excitation modulation and that of the monitoring beam enables kinetics to be studied. Furthermore, by exciting through a polariser and analysing the monitoring beam, the polarisation of the transients may be determined.

Fig 2 The two components of polarisation at 410 nm as a function of phase angle. Modulation frequency 108 Hz. *a*, Parallel polarisation, *b*, perpendicular polarisation.

The modulation excitation spectra of a suspension of purple membrane fragments in water at room temperature are shown in Fig 1, measured at 5 or 10 nm intervals. It can be seen that there are bands associated with the phototransients at 410 nm, 510 nm and 660 nm. In addition, the positive depletion band of the original pigments is observed at 570 nm. Although the 410 nm and 660 nm absorption bands are clearly resolved, that at 510 nm only appears as a shoulder on the depletion band. Its identity as a separate transition is established by observing the region between 500 nm and 600 nm as the phase and modulation frequency is changed, when it is observed that the shape of the absorption band in the 510 nm region changes considerably. More convincing proof comes from polarisation studies which show a sudden drop in the polarisation in the region of 510 nm, suggesting the presence of a transient in antiphase to the 570 nm transient. Moreover, if the 570 nm band is phased out to zero, the 510 nm shoulder is resolved as a distinct band.

Polarisation studies showed that the three major bands are polarised. The bands at 570 nm and 660 nm have polarisations of 0.31 and about 0.25 respectively (Polarisation is defined here as $p = [(I/I_{\perp}) - 1] / [(I/I_{\perp}) + 2]$). This suggests that the pigment is in a fairly viscous environment. The band at 410 nm at first seemed to give an anomalous result, until it was realised that the parallel and perpendicular components of the polarisation at this wavelength are not in phase, as is shown in Fig 2. As a consequence the polarisation obtained varies with the phase setting and the modulation frequency. This indicates the presence of at least two species absorbing at 410 nm with slightly different polarisations and lifetimes.

Attempts to estimate lifetimes using the phase shift proved

Fig 3 Schematic diagram of kinetic processes. The two complexes absorbing at 410 nm may be conformers.

difficult since the apparent values measured varied with modulation frequency. This shows that the kinetics are not first order. The following facts have however been established. The 410 nm and 660 nm bands are in exact phase at low modulation frequency (5 Hz) with an apparent lifetime of about 15 ms, about 1 ms longer than the 570 complex. At high modulation frequency (108 Hz), the 660 nm band has an apparent lifetime of 1 or 2 ms whereas both the 570 and 410 nm bands still have long apparent lifetimes of about 12 ms, that of the 410 nm band again being slightly longer. In comparison the 510 nm transient is very short lived indeed, with a lifetime of well under 1 ms.

A flash photolysis study showed that both the depletion at 570 nm and the transient at 410 nm have lifetimes of the order of 15 ms, but the kinetics are indeed far from first order. It would appear that the depletion band also has several shorter-lived components, one major one having a lifetime of about 3 ms. The 660 nm transient passes through a well-defined cycle, rising with a lifetime of about 3 ms and decaying with a lifetime of about 12 ms.

A complete explanation of the kinetic observations is not possible at this stage, but a number of salient points emerge. First, the 410 nm band represents the primary phototransient in that the majority of molecules not in the ground state would be found in that state. Second, it seems clear that there are at least two species absorbing at 410 nm, most probably conformers with different polarisations and lifetimes. Furthermore, there is a direct kinetic link between the decay of the 660 nm transient and of the longer-lived 410 nm transient as judged from the phase relationship between them. Apparently at least three pathways exist through which the excited pigment can pass. One pathway renews the pigment rather rapidly, as shown by the observation that the phase of the 570 nm species is always slightly ahead of that of the 410 nm species at both high and low chopping frequencies, one renews it through the 410 nm transient, while the longest pathway involves the 660 nm transient. It seems certain that part of the absorption at 410 nm is associated with the transient which absorbs at 660 nm. This would account for their being in phase at the low modulation frequency. Much of the absorption at 410 nm, however, belongs to a slightly shorter-lived species or at least to a species which decays earlier than the one associated with the 660 nm absorption.

A scheme which fits these observations is shown in Fig 3. On absorption of light by the pigment at 570 nm there is a very speedy relaxation on the part of the excitation, reforming the pigment. This is probably a trivial process of relaxation of the excited triplet-state of the original pigment. At the same time there is a quick conversion of the original pigment to the primary transient absorbing at 410 nm which relaxes slowly back to the original pigment. There is another process which over a period of about 3 ms generates the transient absorbing at 660 nm with its associated absorption at 410 nm. This also decays with a long lifetime of about 12 ms to the original pigment.

The phenomena described above were also observed in basal salt⁵, which made little difference to the spectra above 400 nm.

All samples studied were deoxygenated by purging with argon and sealing, in these conditions they were stable over periods of several weeks at room temperature. The addition of valinomycin in excess had only one effect: the 570 nm polarisation increased by about 10%, but it was found that the lifetime of this transient as measured at the 108 Hz modulation frequency decreased to a similar extent. Evidently the valinomycin quenches some of the shorter-lived species such as the triplet-state, allowing less time for rotational relaxation.

The existence of a conformational change of the 410 nm species may provide a mechanism for the proton pump, in which case the species X shown in Fig. 3 must be the original 410 nm species itself.

We thank Arlette Danon for preparing the suspensions of purple membrane and Rafi Kornstein for carrying out the flash spectroscopy. M.A.S. was on sabbatical from the Department of Pure and Applied Physics, The University, Salford.

Inhibition of adenyl cyclase by an exotoxin of *Bacillus thuringiensis*

CERTAIN strains of the insect pathogen *Bacillus thuringiensis* produce a heat-stable exotoxin which is toxic to species from several orders of insects^{1,2} and also affects mammals³⁻⁵. The exotoxin inhibits ecdysone-stimulated insect RNA polymerases of mice both *in vivo*⁶ and *in vitro*⁷.

RNA polymerase catalyses nucleophilic attack by an alcohol group on the α -phosphorus of ribonucleoside triphosphates. Adenyl cyclase also belongs to this functional group of enzymes and in the studies reported here the exotoxin has been shown to be a competitive inhibitor of adenyl cyclase, to inhibit both fluoride and hormonal stimulation of this enzyme activity and to block both adrenocorticotrophic hormone (ACTH)-induced increases in adrenal cyclic adenosine monophosphate (cyclic AMP) and adrenal steroidogenesis.

The effects of exotoxin on pigeon erythrocyte adenyl cyclase were studied first. In intact avian erythrocytes, the activity of this enzyme is increased by adrenaline⁸, while in resuspended haemolysed erythrocyte preparations ('ghosts') adenyl cyclase activity is increased by sodium fluoride⁹. Figure 1 shows that the increased adenyl cyclase activity produced by sodium fluoride in 'ghosts', prepared from adult feral pigeons was markedly inhibited by exotoxin. Exotoxin also inhibited the increased adenyl

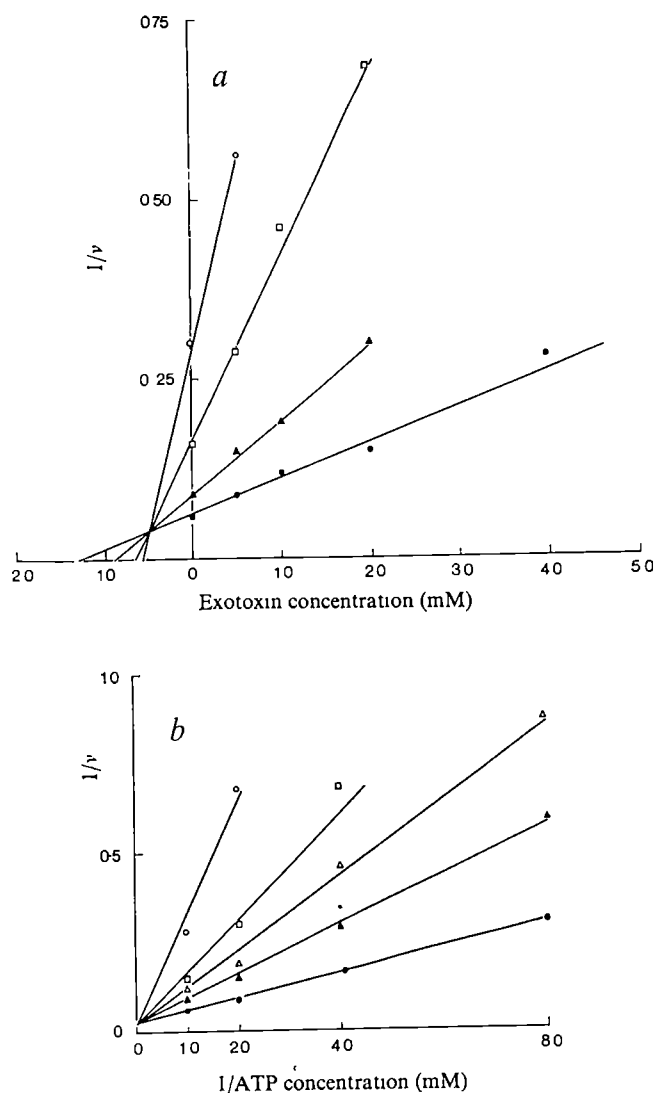

Fig. 1 Inhibition of pigeon erythrocyte adenyl cyclase by exotoxin. To combine results from several experiments, results are expressed as cyclic AMP produced as a percentage of uninhibited adenyl cyclase activity. ○, Erythrocyte 'ghosts' stimulated by sodium fluoride 1×10^{-2} M, ●, intact erythrocytes stimulated by adrenaline 1×10^{-6} M, △, unstimulated level of cyclic AMP production by 200 μ l erythrocyte 'ghosts' suspensions, mean 1.4 ng min^{-1} (range $0.6\text{--}3.0 \text{ ng min}^{-1}$), ▲, unstimulated level of cyclic AMP production by 200 μ l intact erythrocyte suspension, mean 2.2 ng min^{-1} (range $1.4\text{--}3.0 \text{ ng min}^{-1}$). Adult feral pigeons were anaesthetised with pentobarbitone (4 mg per 100 g) injected intramuscularly. Blood was drawn directly from the heart into a heparinised syringe, haemolysed 'ghosts'¹⁰ were prepared from washed erythrocytes⁸. Incubations were performed at 37°C with shaking under 95% $\text{O}_2 + 5\% \text{CO}_2$. The incubation mixture consisted of 200 μ l of the intact or haemolysed erythrocyte suspensions, and ATP (2×10^{-3} M) was added to 'ghost' incubations. A solution of the sodium salt of the exotoxin (5 mg ml^{-1}) was added in increasing volumes, and appropriate volumes of the modified Krebs bicarbonate buffer⁸ containing 6 mM theophylline (in which all added substances were also dissolved) were added to give a final incubation volume of 2 ml. After preincubation of the erythrocyte suspensions for 3 min with exotoxin, adrenaline (final concentration 10^{-6} M) or sodium fluoride (final concentration 10^{-2} M) was added and the incubation continued for a further 5 min. The reactions were terminated by the addition of trichloroacetic acid (TCA) to give a final concentration of 5% (w/v) and the resulting precipitate was removed by centrifugation. The TCA was extracted from the supernatant by shaking with 3 volumes of ether three times. The cyclic AMP in the supernatant was then measured by saturation analysis using the bovine adrenal cyclic AMP binding protein¹¹.

cyclase activity produced by adrenaline in intact erythrocytes, although at low exotoxin concentrations there appeared to be slightly increased cyclic AMP production.

Cyclic AMP is thought to act as the intracellular mediator of the action of many hormones¹². In the adrenal cortex, ACTH stimulates adenylyl cyclase, adrenocortical cell concentrations of cyclic AMP rise, and, by a sequence of reactions not yet fully understood, increased amounts of cholesterol are converted to pregnenolone and increased steroidogenesis ensues. We have studied the effect of exotoxin on this system. Table 1 shows that ACTH produced a 38% increase in cyclic AMP content of the adrenal glands and increased 11-hydroxycorticoid production to 176% of control levels. In the presence of exotoxin, however, ACTH did not produce a significant rise in either cyclic AMP or 11-hydroxycorticoids.

To ensure that exotoxin was not interfering with corticosteroid production independently of its effects on cyclic AMP production, further incubations were performed in which, instead of adding ACTH, cyclic AMP itself was added (final concentration 5×10^{-3} M). This led to a 157% increase in 11-hydroxycorticoid production (Table 1) which was not significantly altered by exotoxin.

These results suggest that exotoxin inhibits the increased activity of adrenocortical adenylyl cyclase produced by ACTH and, therefore, prevents the ACTH-induced rise in adrenocortical cyclic AMP concentrations, concomitantly reducing ACTH-stimulated steroidogenesis. Since cyclic AMP-induced steroidogenesis is not inhibited by exotoxin, other effects of the exotoxin in the mechanisms mediating steroidogenesis distant to the point of action of cyclic AMP were excluded.

The mechanism by which exotoxin inhibits adenylyl cyclase activity was studied in a rat brain preparation. Figure 2 shows that exotoxin competitively inhibits adenylyl cyclase in this preparation with a K_i of 0.5 mM. The K_m for ATP in this preparation was 1.1 mM.

The ability of exotoxin to compete with ATP as a substrate for adenylyl cyclase is probably a property of its structural similarity to the natural substrate. Available evidence suggests that exotoxin differs from ATP in that the 5' position of ribose is substituted with a phospho-allomucyl glucoside rather than a triphosphate^{2,15}. Although a synthetic analogue of ATP, α, β -methylene ATP, has recently been shown to inhibit adenylyl cyclase activity in mammalian liver and fat cell membrane preparations¹⁶, inhibition by other naturally occurring ATP analogues has not previously been reported. 3-Deoxy ATP, isolated from culture filtrates

of the moulds *Cordiceps militans*¹⁷ and *Aspergillus nidulans*¹⁸, inhibits RNA polymerase¹⁹ and seems worthy of study with respect to adenylyl cyclase.

Fig 2 Inhibition of rat brain adenylyl cyclase by exotoxin. a, Effects of altering exotoxin concentration at fixed ATP concentration: ●, No exotoxin; ▲, 0.5 mM; △, 1.0 mM; □, 2.0 mM; ○, 4.0 mM. b, Effects of altering ATP concentration at fixed exotoxin concentration: ATP added: ●, 1.0 mM; ▲, 0.5 mM; □, 0.25 mM; ○, 0.125 mM. v is expressed as nmol cyclic AMP produced per min by the crude mitochondrial fraction derived from 1g brain.

Male Wistar rats (200 g) were decapitated by guillotine, the brain was homogenised in 0.32 M sucrose and a crude mitochondrial fraction (P_2) was prepared¹⁴. The P_2 pellet was resuspended in 10 volumes of 0.3 M Tris-HCl buffer pH 7.4 containing 8 mM theophylline and 3 mM magnesium (v/w original brain wet weight). This suspension was then ultrasonicated for 5 min using a DAWE 1130 Soniprobe producing 75 W at 20 KHz. This mitochondrial preparation (50 μ l) was preincubated at 30°C with sodium fluoride (10 mM) in the presence of exotoxin and an appropriate volume of Tris-HCl-theophylline-magnesium buffer to give a final volume of 200 μ l. After 5 min, ATP was added and the incubation continued for a further 15 min. The reaction was stopped by boiling for 3 min, the precipitate removed by centrifugation and the cyclic AMP content of the supernatant measured.

Table 1 Effects of exotoxin on 11-hydroxycorticoid and cyclic AMP content in rat adrenal quarters*

Additions	11-Hydroxycorticoid content (μ g 100 mg ⁻¹ adrenal gland)		Cyclic AMP content (ng 100 mg ⁻¹ adrenal gland)

* Combined results of ten experiments, † difference significant at $P < 0.01$, ‡ difference not significant, § difference significant at $P < 0.01$.

To achieve basal levels of steroidogenesis and cyclic AMP production adult male Wistar rats (150 g) were anaesthetised with pentobarbitone (6 mg per 100 g) injected intramuscularly and decapitated by guillotine, while unconscious, 1 h later. Quartered adrenal glands were preincubated at 37°C for 90 min in Krebs-Ringer bicarbonate pH 7.4 (1.5 ml) containing glucose 100 mg per 100 ml (KRBG), under 95% $O_2 \times 5\%$ CO_2 . The glands were then removed, blotted dry, weighed and then incubated in 2.5 ml of fresh KRBG under 95% $O_2 \times 5\%$ CO_2 in the presence or absence of 6 mM exotoxin. After 15 min, ACTH (Organon) was added (final concentration 2 U ml⁻¹) and the incubation continued for 60 min. The reaction was then terminated by rapid freezing of the medium and glands in solid CO_2 and acetone. After thawing, the glands were homogenised in the incubation medium. TCA (final concentration 5% w/v) was added to 0.5 ml of the homogenate and the protein precipitate removed by centrifugation. TCA was extracted from the supernatant and the cyclic AMP measured as described in the legend to Fig 1. In addition, 0.5 ml of the homogenate was shaken with 4 ml dichloromethane and the 11-hydroxycorticoid content of the dichloromethane extract measured by fluorimetry¹³.

Bacillus thuringiensis exotoxin appears to be a relatively specific competitive inhibitor of adenylyl cyclase and may prove to be a useful tool in the investigation of the role of adenylyl cyclase and cyclic AMP in various systems. Perhaps the ability of this exotoxin, and other potential adenylyl cyclase inhibitors, to block a cellular physiological response to a hormone could be added to the existing criteria for the involvement of cyclic AMP in hormone actions¹²

Size and DNA content of purified *E. coli* nucleoids observed by fluorescence microscopy

PREVIOUS studies of the physico-chemical properties of DNA as isolated in condensed bacterial chromosomes suggested that the DNA was packaged in particles with dimensions similar to the intracellular nucleoid¹⁻³. This finding, if confirmed, is of significance for it indicates that current methods for isolating the condensed chromosomes preserve the conformational organisation of the DNA at least to the extent that the gross dimensions of the nucleoid are maintained.

Here we demonstrate that the isolated folded chromosomes visualised by fluorescence microscopy have dimen-

sions very similar to those of the intracellular nucleoid. This method also enabled us to determine the DNA content of the nucleoid. We found that the isolated nucleoids contain on average $15 \pm 2 \times 10^{-9}$ μ g of DNA or 3.6 ± 0.5 genome equivalents when doublet, replicating nucleoids were scored as a single structure.

The membrane-free nucleoids were isolated as previously described from *Escherichia coli* strain D-10³. The procedure for fluorescence microscopy was that of Laurent *et al*⁴ who used ethidium bromide as a fluorescent probe to visualise kinetoplast DNA.

Fig 1 Fluorescence micrographs of the nucleoid of *E. coli*. Cells in exponential growth suspended in growth medium containing $20 \mu\text{g ml}^{-1}$ ethidium bromide. The nucleoid can be seen as the brighter body occupying only part of the cell volume. *b*, Membrane-free isolated nucleoids which had been fixed with formaldehyde and suspended in a solution containing 0.01 M sodium phosphate (pH 7.8), 1.0 M NaCl, 1 mM β -mercaptoethanol, 20% sucrose, 1 mM trisodium citrate and $20 \mu\text{g ml}^{-1}$ ethidium bromide. Fixation was accomplished by mixing sucrose gradient fractions containing the isolated nucleoids with formaldehyde to a final concentration of 0.4% v/v. If Tris-EDTA buffer was present Na phosphate buffer was added to 0.05 M final concentration before the formaldehyde. After incubating for 10 min at 20°C , the fixed nucleoids were resedimented through 30% sucrose on to a self of saturated CsCl solution (45 min at 25,000 r.p.m., 4°C in an SW50.1 rotor). A Leitz Orthoplan microscope with an HB 200 mercury lamp was used with a BG 12 excitation filter and a K 510 nm suppression filter. Photographs were recorded on trix-X ASA 400 film. Scale bar represents 5 μm .

Figure 1a shows a fluorescence micrograph of exponentially growing cells after addition of ethidium bromide. The high spot of intensity is the nucleoid which appears to nearly fill the width of the bacterium but not its length. At the same magnification, the isolated nucleoids (Fig 1b) appear very close in size to the intracellular nucleoid. They range in size from 0.5 to 1.5 μm . Before fluorescence microscopy the isolated nucleoids were fixed by reaction with formaldehyde⁵. Unfixed nucleoids appeared very similar to those shown in Fig 1, however, they were less stable to the conditions of fluorescence microscopy and they gradually expanded and became more diffuse during the microscopy (our unpublished observations). Such changes were not observed with the fixed particles. The fluorescence intensity of the isolated nucleoids is reduced relative to nucleoids

Table 1 Determination of DNA content per nucleoid

Nucleoid concentration per ml ($\times 10^{-6}$)			Concentration of radioactivity in nucleoids c p m ml $^{-1}$ ($\times 10^{-5}$)	Specific Activity of DNA c p m μ g $^{-1}$ ($\times 10^{-5}$)	Average μ g DNA per nucleoid ($\times 10^{-9}$)		Average genome equivalents per nucleoid	
Singles (S)	Doubles (D)	Total (S + D)			S + 2D	S + D	S + 2D	S + D
24 \pm 6	52 \pm 4	76 \pm 10	50	43	91 \pm 10	15 \pm 2	22 \pm 0.2	36 \pm 0.5
					94 \pm 10	15 \pm 2	22 \pm 0.2	36 \pm 0.5

A culture of cells (30 ml) was labelled for 20 min with 100 μ C of 3 H-thymidine (55 Ci mmol $^{-1}$) just before collection of the cells. Generation time of the cells was 29 min. Nucleoids were isolated from a portion of the culture and DNA was purified from the remainder. The method for DNA purification included lysis with lysozyme and sodium dodecyl sulphate, repeated cycles of phenol extraction, three cycles of RNase treatment interspersed with ethanol precipitations and resuspension, and passage through a BioRad P-100 column. The specific radioactivity of the DNA is listed above. The nucleoid concentration in the preparation was determined in a Petroff-Hausser chamber as described in Fig. 1. Both single (S) and double nucleoids (D) were scored. The first line of the Table shows the result of a single measurement averaged over 304 nucleoids. The second line is an average of all our data over 2,379 nucleoids. The calculated DNA content per nucleoid and the number of genome equivalents per nucleoid are tabulated above assuming, on the one hand, that there are two nucleoids per doublet and, on the other hand, that there is one nucleoid per doublet. Radioactivity was counted in a Packard liquid scintillation system, it was determined that 3 H counting efficiencies of the purified DNA and purified nucleoids were the same and hence corrections were not required.

in situ when examined as in Fig. 1. This reduction is at least partially attributable to the higher salt concentrations added to stabilise the purified nucleoids. These salt concentrations are known to increase the dissociation coefficient of ethidium bromide bound to DNA⁵.

When ethidium bromide binds to the DNA of isolated nucleoids it can affect the amount of supercoiling in the structure and thereby alter the state of condensation of the DNA^{2,7}. However, as indicated from previously published hydrodynamic properties of the nucleoids^{2,7}, the conditions and concentration of ethidium bromide used in the present work should not significantly influence the final dimensions of the nucleoids. We have also demonstrated in recent work (unpublished work) that the sedimentation rate of fixed nucleoids as shown in Fig. 2 changes by less than 10% in the presence of these concentrations of ethidium bromide.

Fig. 2 Sedimentation of fixed nucleoids. After completing the observations described in Fig. 1 and Table 1, an aliquot of the same preparation of fixed nucleoids was diluted, 14 C-T4 phage added as a sedimentation marker (1,025S) and sedimented for 30 min at 4°C and 17,000 r.p.m. through a 10–30% w/v sucrose gradient containing 0.01 M Na phosphate (pH 7.8), 1 mM trisodium citrate and 1.0 M NaCl. ○ 14 C-T4 phage, ● 3 H-DNA in nucleoids.

Rapidly growing cells, such as those observed in this study, frequently contain a pair of nucleoids. When this occurs the two bodies usually seem to be separated towards the opposite poles of the cell (see ref. 8). We also observed a significant number of doublets in the preparations of purified nucleoids (Fig. 1b and Table 1). These were not generated by the fixation treatment since doubles were observed at about the same frequency in unfixed preparations of nucleoids. Resedimentation of the fixed nucleoids confirms the absence of any aggregation as well as reproducing the 1,600S average sedimentation rate of unfixed nucleoids relative to a T4 phage marker (Fig. 2). From these results, it seems likely that nucleoid pairs in the cells may actually be connected and that these connections are preserved during the isolation. Possibly the nucleoids that seem to be separated yet occur in doublets have not yet completed their division.

The concentration of nucleoids in a preparation can be measured conveniently using fluorescence microscopy techniques. From this approach we were able to determine the average DNA content of the isolated fixed nucleoids (Table 1). Depending on whether the double nucleoids were scored as a single body or two, the calculations show that on average the isolated nucleoids are made up of respectively, 3.6 or 2.2 genome equivalents of DNA (A genome equivalent of DNA is the mass of DNA corresponding to a single, non-replicating chromosome). When doublets are counted as a single nucleoid, the DNA content per nucleoid agrees closely with the cellular DNA content of *E. coli* cells grown under similar conditions^{9,10}. This finding offers further support to the above proposal that each of the doublets observed in our preparations was associated as a pair of nucleoids in a single cell.

In scoring the nucleoids for shape, the distinction between the doublet and singlet was not always clear. It was our impression that there may be a continuum in the degree of separation of the nucleoid halves. With this in mind it should be stressed that the distribution between doublets and singlets described in Table 1 was necessarily subjective.

After completing all of the microscopy measurements described in Fig. 1 and Table 1, an aliquot of the fixed nucleoids was resedimented on a sucrose gradient to assess the extent of unfolding or aggregation of the nucleoids which may have occurred during handling or storage. As Fig. 2 shows, the fixed nucleoids maintained their condensed state and the mean sedimentation rate of the particles was indistinguishable from the rate observed immediately after isolation^{6,7}.

In conclusion, we have shown by direct visualisation of the isolated nucleoids by fluorescence microscopy that the chromosomal DNA is isolated in a structure similar in size and DNA content to the nucleoids observed *in vivo*.

Polyamines stabilise DNA folds

THE DNA of bacterial cells, gently isolated in the presence of high concentrations of monovalent salts, remains folded in a particle resembling the bacterial nucleoid^{1,2}. The double-helical DNA is condensed by folding¹ and by supercoiling³ and the compact structure is dependent both on counterions in the solvent environment and RNA molecules bound to the DNA¹⁻⁴. In the absence of these stabilising interactions the DNA unfolds and acquires the usual properties of extended

Fig. 1 Sedimentation of folded and unfolded DNA after various periods of storage. Membrane-free nucleoids labelled with ³H-thymidine were isolated on sucrose gradients containing 1.0 M NaCl and other components as described in text, peak fractions were pooled and half of the pool was stored at 4° C. The other half was also stored at 4° C but in the presence of 5 mM spermidine and with NaCl diluted to 0.25 M while holding other components of the gradient buffer constant. At various times aliquots were removed, diluted to approximately the same DNA concentration (0.5-1.5 µg ml⁻¹) and ¹⁴C-labelled T4 phage (1.025S, ref 7) were added as a sedimentation marker. The mixture was layered on a 4.8 ml sucrose gradient (10-30% w/v) containing 0.4 M NaCl, 1.0 mM spermidine and other components as described in the text and centrifuged at 17,000 r.p.m. at 4° C for 30 min in a SW50.1 rotor. The DNA was stored in 1.0 M NaCl for 1 h (a) or 6 d (c) in 0.25 M NaCl plus 5 mM spermidine for 1 h (b) or 6 d (d). ○, ³H-DNA, ●, ¹⁴C-T4 phage

double-helical DNA^{1,3}. The concentrations of monovalent salts required during the isolation of folded DNA are significantly greater than those found in the cell. It is, however, believed that *in vivo* polyamines may be an important counterion neutralising DNA⁵. We have now found that moderate concentrations of the polyamine spermidine greatly stabilise the condensed DNA conformations in isolated nucleoids. In addition to broadening current understanding of the role of counterions in stabilising condensed DNA states, this finding will be of significance to studies in which the stability of the nucleoid *in vitro* is important.

Nucleoids were isolated from *E. coli* strain D-10 as before^{1,2}. We used the membrane-free nucleoid² (1,600S), obtained by incubating the lysate before DNA isolation at 20° C in the presence of 0.5% Brij 58-0.2% deoxycholate. The folded DNA of this particle has less than 10% by weight bound protein, most of which is DNA-dependent RNA polymerase^{1,2,6}. Nascent RNA chains are also bound to the folded DNA, the RNA fraction is 0.4 relative to DNA (w/w) (ref 2). In some cases purification was on sucrose gradients containing 0.01 M Tris (pH 8.1), 1 mM EDTA, 1 mM β-mercaptoethanol and 1.0 M NaCl, in other cases, the gradients contained the same mixture, but with 0.4 M NaCl and 1 mM spermidine. The results described here were similar using both kinds of preparations.

Fig. 2 Stabilisation of folded DNA with spermidine. Isolated nucleoids were stored at 4° C in the presence of varied amounts of spermidine and at times later were sedimented as described in Fig. 1 to estimate the level of unfolding (see text for definition of 'folded'). □, 1.0 M NaCl minus spermidine, x, 0.10 M NaCl minus spermidine, other points had 0.25 M NaCl plus spermidine: 10 mM (●), 5 mM (Δ), 2 mM (○), or 1 mM (■).

As Fig. 1a shows, the folded DNA immediately after isolation sedimented at about 1,600S in a band somewhat broader than that of a homogeneous molecular weight marker. Worcel and Burgi³ have demonstrated that the slight heterogeneity is attributable to the variation in DNA content of nucleoids in different stages of replication. During prolonged storage, with monovalent salts as the stabilising counterions, the DNA gradually unfolded and we observed transition to slower sedimenting structures (Fig. 1c). The evidence that the sedimentation change was derived primarily from conformational alteration of the DNA rather than a reduction of the mass or molecular weight of the structure is essentially the same as reported¹⁻⁴. As in the case of the transition resulting from

Fig 3 Thermally induced unfolding in the presence or absence of spermidine. Isolated nucleoids were diluted to the same DNA concentration in different solutions so that all components of the storage buffer remained constant (see Fig 1) but the NaCl concentration became 0.1 M and the spermidine concentration was 5 mM (Δ) and 2 mM (\circ) or none was added (\square). The solutions were heated for 5 min at the temperatures shown, chilled to 0°C and sedimented as described in Fig 1 to estimate the level of unfolding.

treatment with reagents which unfold the DNA, there was a simultaneous large increase in relative viscosity and reduction in sedimentation rate. Also, since the mass of the isolated nucleoid is due predominantly to DNA, any dissociation of RNA or protein should by itself not have led to a large reduction in sedimentation rate. Furthermore, our preliminary sedimentation studies (unpublished) of DNA obtained from partially unfolded nucleoids indicate no large change in DNA molecular weight.

To describe the changes that occur in data such as those of Fig 1, we use the following rough criterion. Folded DNA is said to have been unfolded or partially unfolded if, without breaking the DNA, it undergoes transition from a structure sedimenting more rapidly than 1,000S to one sedimenting at less than 1,000S. Until there is a more quantitative understanding of unfolding this criterion will suffice for approximation.

The rate of DNA unfolding during storage was reduced in the presence of spermidine (Fig 1). As Fig 2 shows, unfolding rate was minimal with 5 or 10 mM spermidine and increased with lower concentrations. In the absence of spermidine the nucleoids were not stable for more than a few days, however, they were much more stable in 1.0 M than in 0.1 M NaCl.

Spermidine also stabilised against thermally induced unfolding (Fig 3). In a solvent containing 0.1 M NaCl and 2 mM spermidine the temperature at which half of the nucleoids were partially unfolded appears to be approximately 55°C measured under the conditions described in Fig 3, while it increased to more than 70°C in the presence of 5 mM spermidine. In the same solvent without spermidine the analogous temperature was about 15°C and nearly all the DNA was partially unfolded at 37°C (see Fig 4 for relevant sedimentation profiles). The sharpness of the thermally induced transition suggests that the molecular interactions stabilising folded DNA, like those stabilising the double helix, are cooperative. By comparison the T_M for denaturation of double helical *Escherichia coli* DNA in the same solvent without

spermidine was 85°C and with 5 mM spermidine added it increased to about 90°C.

The sedimentation method used here to observe the unfolding transition, is particularly sensitive to partial unfolding of DNA⁴. Using the criterion described above, DNA which has partially unfolded and sediments at rates less than 1,000S is scored the same as completely unfolded DNA. One would therefore expect that when precise methods are available for quantitating the amount of unfolding, the transition temperatures required to remove half of the DNA folds will be somewhat larger than our estimates.

We occasionally observed an apparent aggregation of isolated nucleoids mediated by spermidine. This was most obvious at the highest spermidine concentrations (above 2 mM) and at the lowest DNA concentrations (less than 1 μ g DNA ml⁻¹). It was manifested by an increased sedimentation rate and increasingly broad sedimentation profile of the nucleoids. In extreme cases at high spermidine concentrations complete precipitation of the nucleoids was observed using the sedimentation conditions described in Fig 1.

Fig 4 Sedimentation profiles of folded DNA after heating. Three sucrose gradients from the data summarised in Fig 3 are shown: (a) 37°C minus spermidine, (b) 37°C, 2 mM spermidine, (c) 60°C, 5 mM spermidine. \circ , ³H-DNA; \bullet , ¹⁴C-T4 phage.

Polyamines are known to stabilise different nucleic acid structures and protein-nucleic acid complexes. Examples are such interactions with double-helical DNA^{8,9}, viruses¹⁰, ribosomes^{11,12} and triple-stranded nucleic acid structures¹³. Polyamines also stimulate *in vitro* a wide range of different enzymatic reactions (see ref 5 for review). The results described here show that stabilisation of condensed DNA in bacterial chromosomes by spermidine cannot be replaced even by very high concentrations of monovalent salt. It seems possible that the bifunctional character of spermidine could permit a linking interaction with two closely packed regions of a DNA double helix or at the site of an RNA-DNA association.

Position of regularly spaced single-stranded regions relative to 5-bromodeoxyuridine-sensitive sites in sea urchin morula DNA

5-BROMODEOXYURIDINE (BUdR) inhibits cell differentiation and embryogenesis and yet has little effect on cell division or metabolism¹. When sea urchin embryos are grown in the presence of BUdR, pre-gastrula DNA accumulates as 30–60S duplex pieces². We have now found that naturally occurring, regularly spaced, single-stranded regions in morula DNA³ are the sites at which BUdR-induced breakage occurs, resulting in production of these 30–60S low molecular weight DNA pieces. The DNA pieces from morulae grown in BUdR are approximately half the length of DNA molecules from control embryos grown in thymidine (TdR).

In the labelled DNA preparations used at least 85% of the isolated radioactivity is covalently bonded, as determined by enzymatic and alkaline hydrolysis². Also, ³²P-DNA should represent only nuclear sequences since mitochondrial DNA is not synthesised until after the morula stage^{4,5}. Both of these points have been confirmed by CsCl buoyant density centrifugation of morula ³²P-DNA. Based on density centrifugation, we calculated that approximately 41% of the TdR residues in ³²P-DNA isolated from morulae grown in the presence of BUdR (50 µg ml⁻¹) are BUdR-substituted (S T C, unpublished data).

The effect of *Aspergillus oryzae* single-strand specific S₁ nuclease⁶ on the sedimentation profile of morula DNA was examined on neutral sucrose gradients. DNA was isolated from control culture embryos grown from fertilisation in the presence of 50 µg ml⁻¹ TdR and ³²P. The DNA was mixed with a reaction buffer optimised for S₁ nuclease activity and divided into two equal portions. S₁ nuclease was added to one half while the other was a control without enzyme. Both were centrifuged through sucrose gradients as described in Fig 1. The bulk of labelled morula DNA sedimented as a single zone (Fig 1a) at approximately 51.3S (Table 1). When previously treated with S₁ nuclease, this DNA sedimented more slowly with a peak value of 39.8S (Fig 1b, Table 1).

The effect of S₁ nuclease treatment on the sedimentation profile of morula ³²P-DNA, isolated from embryos grown in the presence of BUdR, was also examined on neutral sucrose gradients. The major portion of this DNA sediments at about 42.7S (Fig 2a, Table 1). After S₁ nuclease treatment, this BUdR-substituted DNA is reduced to a predominant size-class having a peak sedimentation value of 31.1S (Fig 2b, Table 1). Thus, the bulk of the BUdR-substituted duplex DNA sedimented more slowly than the corresponding DNA

Fig 1 Effect of S₁ nuclease on neutral sucrose sedimentation profiles of morula ³²P-DNA isolated from embryos grown in the presence of TdR. (a) ³²P-DNA incubated without addition of S₁ nuclease, (b) ³²P-DNA incubated with S₁ nuclease. *Strongylocentrotus purpuratus* embryos were cultured¹⁴ in artificial seawater¹⁵. TdR was added to 50 µg ml⁻¹ and ³²P was added to 0.5 µCi ml⁻¹ at 5 and 10 min, respectively, after fertilisation and were both present throughout the growth period. Development was terminated and DNA extracted as previously described². 200 µg of ³²P-DNA (specific activity, 650 c.p.m. µg⁻¹) was mixed with a buffer providing final concentrations of 0.15 M NaCl, 0.03 M sodium acetate, pH 4.5, and 10⁻⁴ M ZnSO₄. 25 U (ref 16) of S₁ nuclease were mixed with 100 µg of ³²P-DNA while the remaining 100 µg of DNA was the control without S₁ nuclease. Both samples were incubated at 40° C for 45 min and the enzymatic reaction was terminated by chilling the samples and adding 10⁻¹ volume of 0.5 M EDTA. 50 µg of ³²P-DNA from each reaction mixture was combined with 10 µg ³H-TdR-labelled φ80 phage DNA, brought to a final volume of 1 ml with 0.15 M NaCl, 0.015 M sodium citrate and layered on to a 30 ml 5–20% linear sucrose gradient made in 1 M NaCl, 0.02 M Tris-HCl, pH 7.3, and 1 mM EDTA. Centrifugation was in a Beckman SW 25.1 rotor at 24,000 r.p.m. for 7 h at 20° C. Approximately 1.2 ml fractions were collected from the bottom of the centrifuge tubes and the DNA precipitated by the addition of 2 ml of 10% trichloroacetic acid and 50 µg bovine serum albumin. Samples were collected on Whatman GF/A filters and counted in a toluene-based scintillation fluid. ○, ³H, ●, ³²P.

Table 1 Effect of S₁ nuclease treatment on sucrose gradient sedimentation characteristics of ³²P-DNAs isolated from sea urchin morulae grown in the presence of either TdR or BUdR

	S ₁ treated	Neutral gradients			Alkaline gradients		
		Peak S _{20,w}	Molecular weight × 10 ⁻⁶	Base pairs × 10 ⁻³	Peak S _{20,w}	Molecular weight × 10 ⁻⁶	Bases × 10 ⁻³
TdR	—	51.3	97.7	148.1	38.9	14.8	44.8
	+	39.8	46.3	70.2	34.8	11.1	33.8
BUdR	—	42.7	57.5	87.1	38.3	14.2	43.0
	+	31.1	23.1	35.0	35.4	11.6	35.2

Neutral sedimentation data were obtained from Figs 1 and 2. Alkaline sedimentation data were obtained by centrifugation of 50 µg of sea urchin ³²P-DNA mixed with 10 µg of ³H-φ80 phage DNA. The DNAs were made 0.2 M NaOH and held at 37° C for 30 min before layering on to 30 ml 5–20% linear sucrose gradients made in 0.1 M NaOH, 0.9 M NaCl, 1 mM EDTA. Conditions of centrifugation were the same as described in Fig 1. Conditions for S₁ nuclease treatment are given in Fig 1. S_{20,w} values were determined by the relative sedimentation distance of ³H-φ80 phage DNA as marker, cosedimented in each gradient. Molecular weight was calculated from S_{20,w} values using the equations of Studier¹². The calculated S_{20,w} value for φ80 phage DNA is 33.4 based on a molecular weight of 28.6 × 10⁶ (ref 13). For neutral sucrose gradients, calculations were based on continuous (gap-free) double-stranded pieces.

isolated from embryos grown in the presence of TdR. In addition, S₁ nuclease treatment reduced the sedimentation rate of the BUdR-substituted DNA even more than the enzyme affected DNA isolated from control embryos.

The effect of S₁ nuclease on sedimentation profiles obtained for morula ³²P-DNA isolated from cultures grown in the presence of TdR or BUdR was examined on alkaline sucrose gradients (Table 1). Non-enzyme-treated DNA, isolated from a control culture, sedimented as a single region of radioactivity at 38.9S. When treated with S₁ nuclease before denaturation, this DNA sedimented as a zone at 34.8S in alkali. ³²P-labelled BUdR-containing DNA had an approximate sedimentation value of 38.3S in alkaline sucrose. An equivalent sample of this latter DNA, treated with S₁ nuclease before denaturation, sedimented as a sharp zone at 35.4S. While the bulk of native BUdR-substituted DNA was approximately half the length of

native DNA isolated from control embryos, alkaline denaturation of either of these DNAs resulted in molecules of approximately equal size and about one-fourth the length of the native DNA from control embryos (Table 1). Digestion of single-stranded regions by S_1 nuclease before denaturation slightly reduced the size of both the resulting single-stranded control and BUdR-substituted DNAs to approximately equal-length pieces (Table 1).

Fig 2 The effect of S_1 nuclease on neutral sucrose sedimentation profiles of morula ^{32}P -DNA isolated from embryos grown in the presence of BUdR. (a) ^{32}P -DNA incubated without the addition of S_1 nuclease, (b) ^{32}P -DNA incubated with S_1 nuclease. Embryos were grown and ^{32}P -DNA extracted as described in Fig 1 except that TdR was replaced by BUdR ($50\text{ }\mu\text{g ml}^{-1}$). $200\text{ }\mu\text{g}$ of ^{32}P -DNA (specific activity, $450\text{ c.p.m. }\mu\text{g}^{-1}$) was mixed with NaCl-sodium acetate- ZnSO_4 , $100\text{ }\mu\text{g}$ of the DNA was treated with S_1 nuclease while the remaining $100\text{ }\mu\text{g}$ was incubated without enzyme. $50\text{ }\mu\text{g}$ of both the control and S_1 nuclease treated ^{32}P -DNAs were mixed separately with $10\text{ }\mu\text{g}$ of ^3H -TdR-labelled $\phi 80$ phage DNA. Conditions for sedimentation and collection of samples were identical to those described in Fig 1. \circ , ^3H ; \bullet , ^{32}P .

A model is presented in Fig 3 for the structure of morula DNA based on the neutral and alkaline sucrose sedimentation data summarised in Table 1. While length determinations of DNA molecules on sucrose gradients are rather imprecise, the proportional molecular lengths corresponding to the peak sedimentation values obtained are in good agreement with the model. Duplex DNA molecules isolated from morula stage embryos are smaller than one would predict for chromosome-length DNA^{7,8} and thus presumably represent subunits. Each subunit of DNA from control (TdR) embryos, represented by L in Fig 3a, must contain a centrally located S_1 nuclease-sensitive site since treatment with the enzyme produces duplex fragments approximately half the length ($1/2\text{L}$ in Fig 3a) of the L molecule. Alkaline denaturation of the original duplex molecule (L) or the duplex fragments generated by S_1 nuclease ($1/2\text{L}$) yields single stranded DNA pieces one-fourth the length ($1/4\text{L}$ in Fig 3a) of the original subunit. Thus, while each L molecule contains one centrally located S_1 nuclease site, each $1/2\text{L}$ molecule contains one centrally located alkali-sensitive site. The S_1 nuclease and alkali-labile sites in native DNA must

each consist of an interruption in one strand, followed closely by an interruption in the other strand of the duplex molecule. Thus, native DNA is held together at an S_1 site or an alkali-sensitive site by hydrogen bonding of the resulting overlapping cohesive single-stranded regions. If the one S_1 site and the two alkali-sensitive sites on an L molecule were the result of discontinuities in only one strand, denaturation would produce one L and four $1/4\text{L}$ single-stranded molecules. A single peak of sedimentation under alkaline conditions supports the assertion that there are discontinuities in both strands of the native L molecule. Perhaps the difference between an S_1 nuclease site and an alkali-labile site in morula DNA is that the S_1 site is a pair of adjacent gaps while the alkali-labile site is a pair of adjacent nicks. Gaps are sensitive to both S_1 nuclease and denaturation while nicks are insensitive to the enzymatic treatment under the conditions used.

Fig 3 A model of the relationship of regularly spaced S_1 nuclease sites and BUdR-sensitive sites in sea urchin morula DNA.

In previous work³, the average size of morula ^3H -DNA was reported to be somewhat less than that of the equivalent ^{32}P -DNA measured here. Since ^3H -radiation damage to DNA^{9,10} occurs at a faster rate than ^{32}P -radiation damage¹¹ and since the ^{32}P -DNA preparations were used as soon as possible after labelling, we believe that the larger sedimentation values reported here are more accurate.

The duplex DNA molecules isolated from embryos exposed to BUdR are equivalent in length to $1/2\text{L}$ molecules (Fig 3b). Unlike the TdR- $1/2\text{L}$ molecules, however, the BUdR- $1/2\text{L}$ molecules have a central S_1 nuclease sensitive site. Production of BUdR- $1/2\text{L}$ molecules may have resulted from excision *in vivo* of short regions in the L molecules or possibly from a deficiency in joining of $1/2\text{L}$ molecules.

Deficiency of the Y base in a hepatoma phenylalanine tRNA

THE structures of various tRNAs are of considerable interest as this type of RNA plays a central role in translation of the genetic code and has been shown in bacteria to function in cell regulation^{1,2}. In the search for a possible role of tRNA in regulatory processes in higher organisms, a number of studies have compared chromatographic profiles of tRNA from different tissues, organs, tumours and cell cultures³. These studies have revealed that tumour cells frequently contain tRNA species which differ in their chromatographic mobility from the corresponding tRNAs present in normal adult tissues. Until now, however, no structural basis for these tRNA differences between normal and malignant tissues has been elucidated.

One of the most consistent differences reported for tumour tRNAs involves phenylalanine tRNA (tRNA^{Phe}). Several laboratories have demonstrated by reverse phase column chromatography that certain chemically induced rat hepatomas contain, in addition to the single species of tRNA^{Phe} found in normal rat liver, an early eluting peak not normally found in rat liver^{4,5}. It is known that tRNA^{Phe} of normal eukaryotic cells contains a highly fluorescent and hydrophobic base, called Y, which is located next to the 3'-end of the anticodon⁶. The Y compound represents the most highly modified nucleic acid base characterised so far, consisting of a tricyclic imidazo derivative of guanine to which is usually attached a 4-carbon side chain⁷. In this report we present evidence that the additional species of tRNA^{Phe} found in rat hepatomas differs from normal liver tRNA^{Phe} by the absence of the Y base. Our results constitute the first elucidation of a structural difference between a single species of tRNA from malignant cells compared with the corresponding tRNA from normal cells.

Normal rat liver tRNA was aminoacylated with ¹⁴C-phenylalanine and cochromatographed on a RPC-5 column⁸ with tRNA from Morris hepatoma 7777 aminoacylated with ³H-phenylalanine. Figure 1a shows, in agreement with other

Fig 1 Elution profiles of liver and hepatoma tRNA^{Phe} from RPC-5 columns. *a*, ³H-phenylalanyl-tRNA from Morris hepatoma 7777 cochromatographed with ¹⁴C-phenylalanyl-tRNA from normal rat liver (○). tRNA was prepared essentially according to Fink *et al*¹⁴. Crude aminoacyl-tRNA synthetase preparations were obtained from homogenates of normal liver in medium containing 0.01 M Tris-HCl (pH 7.5), 0.1 M KCl, 5 mM MgCl₂, 0.3 M sucrose and 0.014 M β-mercaptoethanol. After removal of cellular membranes and ribosomes by centrifugation at 105,000g for 2 h, the supernatant was passed over a Sephadex G-50 column, and the void volume containing the enzymes was collected and stored in 50% glycerol at -20°C. Labelled tRNA^{Phe} was prepared by incubating 0.5-1 mg tRNA from liver or Morris hepatoma 7777 with aminoacyl-tRNA synthetase (3.1 mg protein) in a 1 ml reaction mixture containing 10 mM KCl, 10 mM MgCl₂, 4 mM ATP (neutralised), 0.6 mM CTP (neutralised), 0.1 M Tris-HCl (pH 7.3), 0.2 mM each of nineteen amino acids (minus phenylalanine), and either 5 μCi ¹⁴C-phenylalanine (specific activity 460 Ci mol⁻¹), or 100 μCi of ³H-phenylalanine (specific activity 7 Ci mmol⁻¹) for 20 min at 37°C. The labelled tRNA^{Phe} was isolated by applying the entire reaction mixture to a 22 × 22 cm DEAE-cellulose column (DE 52 Whatman). The column was washed with 60 ml of starting buffer (50 mM acetate (pH 4.5), 1 mM MgCl₂, 0.4 mM EDTA), proteins were eluted with 20 ml 0.3 M NaCl in starting buffer, and finally tRNA^{Phe} was eluted with 10 ml 0.6 M NaCl in starting buffer. After precipitation of tRNA^{Phe} with two volumes of ethanol at -20°C, it was dissolved in 0.5 ml of starting buffer and applied to a RPC-5 column⁸. The column (0.7 × 17 cm) was eluted with a 100 ml linear gradient of 0.6-0.7 M NaCl in starting buffer at 250 pound inch⁻². Fractions (1.2 ml) were collected at a flow rate of 2 ml min⁻¹, 0.1 ml aliquots were precipitated with 1 ml 10% trichloroacetic acid at 4°C, filtered on to Millipore filters, dried and counted in a liquid scintillation spectrometer. *b*, ¹⁴C-phenylalanyl-tRNA_Y from liver (○) cochromatographed with ³H-phenylalanyl-tRNA from Morris hepatoma 7777 (●). Liver tRNA (20 A₂₆₀ units) was incubated in 0.5 ml of 0.05 M citrate buffer, (pH 2.9) for 18 h at 37°C, reprecipitated with 2 ml ethanol at -20°C, aminoacylated and processed as described in (a).

results^{4,5}, that rat liver contained only one and hepatoma tRNA two, tRNA^{Phe} species. The major hepatoma peak (tRNA₂^{Phe}) eluted in the same position as rat liver tRNA^{Phe}

Table 1 Poly (U)-directed ribosomal binding of hepatoma ³H-phenylalanyl-tRNAs

tRNA species	³ H-phenylalanyl-tRNA (pmol added)	pmol bound		Δpmol bound
		(-Poly(U))	(+Poly(U))	
Experiment 1				
tRNA ₁ ^{Phe}	11.7	1.9	5.9	4.0
tRNA ₂ ^{Phe}	16.6	3.1	15.4	12.3
Experiment 2				
tRNA ₁ ^{Phe}	7.8	1.4	4.4	3.0
tRNA _{2a} ^{Phe}	7.8	2.7	2.5	-0.2
tRNA _{2b} ^{Phe}	10.4	1.3	8.2	6.9

The ribosomal binding assay was essentially that of Nirenberg and Leder¹³. In experiment 1 the incubation mixture contained in 50 μl 1.3 A₂₆₀ *Escherichia coli* ribosomes, 0.02 M Mg²⁺, 0.1 M Tris-HCl (pH 7.2), 0.05 M KCl, 0.5 μg Poly(U) and ³H-phenylalanyl-tRNA from Morris hepatoma 7777 as indicated. Incubations were carried out at 24°C for 20 min, then diluted with three volumes of the incubation buffer, filtered on to Millipore membrane filters and washed extensively with the same buffer. Radioactivity was measured in a Nuclear Chicago Mark II liquid scintillation spectrometer (1 pmol = 385 c.p.m.).

In experiment 2 the incubation system contained in 100 μl 2.6 A₂₆₀ ribosomes, 1 μg poly(U) and hepatoma ³H-phenylalanyl-tRNAs after acid treatment and separation on RPC-5 columns as shown in Fig 2a and b. Other details were as in experiment 1.

The minor hepatoma peak (tRNA₁^{Phe}) eluted at a lower salt concentration

The earlier elution of tRNA₁^{Phe} suggested that it might lack the very hydrophobic Y base which is present in liver tRNA^{Phe} and hepatoma tRNA₂^{Phe}. This base can be selectively excised from tRNA by mild acid treatment without breaking the polynucleotide chain⁹. tRNA modified in this way (tRNA_{-Y}) can be aminoacylated with phenylalanine, although its codon recognition is impaired^{9,10}. Figure 1b shows the results obtained when rat liver tRNA was incubated at pH 2.9 for 18 h to remove its Y base, aminoacylated with ¹⁴C-phenylalanine and cochromatographed on RPC-5 with hepatoma ³H-phenylalanyl-tRNA (Fig. 1b). After acid treatment, the normal tRNA_{-Y} eluted at a lower NaCl concentration and in a position similar to, but slightly earlier than, hepatoma tRNA₁^{Phe}.

We also isolated hepatoma tRNA₁^{Phe} and tRNA₂^{Phe} on an RPC-5 column. Each was incubated at pH 2.9 for 2 h and rechromatographed separately on RPC-5 columns. The elution position of tRNA₁^{Phe} was unchanged by the acid treatment since the peak appeared at fraction 25 before or after pH 2.9 treatment (compare Figs 1a and 2a). On the other hand, acid treatment of hepatoma tRNA₂^{Phe} (Fig. 2b) resulted in the formation of an earlier eluting fraction (tRNA_{2a}^{Phe}) corresponding to the elution position of normal liver tRNA_{-Y} (Fig. 1b). Acid treatment for 2 rather than 18 h does not completely remove the Y base (compare Figs 1b and 2b). Acid treatment of hepatoma tRNA for 18 h, however, also failed to alter the elution position of hepatoma tRNA₁^{Phe} although it converted 100% of hepatoma tRNA₂^{Phe} to earlier eluting material (separate studies not shown here). These results indicate that hepatoma tRNA₂^{Phe} contains the Y base, but hepatoma tRNA₁^{Phe} does not.

Fig 2 RPC-5 elution profile of acid treated (a) ³H-phenylalanyl-tRNA₁ and (b) ³H-phenylalanyl-tRNA₂ from Morris hepatoma 7777. ³H-phenylalanyl-tRNA₁ or ³H-phenylalanyl-tRNA₂ separated on a RPC-5 column (not shown here but identical to separation as in Fig. 1a) were incubated in 0.05 M citrate buffer (pH 2.9) for 2 h, directly applied to an RPC-5 column and processed as described in the legend to Fig. 1.

Since liver tRNA_{-Y} can accept phenylalanine but is impaired in ribosomal binding^{9,10} we studied poly(U)-directed ribosomal binding of the two species of hepatoma tRNA^{Phe} before and after acid treatment. In agreement with previous studies⁴ we found that before the acid treatment both species were active in this reaction (Table 1, experiment 1). When hepatoma tRNA₂^{Phe} was treated with acid, a portion of the material now eluted in the early region of the RPC-5 column (designated tRNA_{2a}^{Phe}). When this material was assayed, it failed to participate in poly(U)-directed ribosomal binding (Table 1, experiment 2). Similar results were

obtained with normal liver tRNA^{Phe} (data not shown). These findings extend previous studies with yeast tRNA^{Phe} indicating that removal of the Y base leads to loss of codon recognition^{9,10}. On the other hand, we found that acid treatment of hepatoma tRNA₁^{Phe} did not impair its ability to participate in codon recognition (Table 1, experiment 2).

These experiments indicate that hepatoma tRNA₁^{Phe} does not contain the fluorescent and hydrophobic Y base normally present in rat liver tRNA^{Phe}, as its elution position on an RPC-5 column did not change after acid treatment and it retained its binding capacity to ribosomes in the presence of poly(U).

Because excision of the base from normal liver tRNA^{Phe}, and from the major tRNA^{Phe} present in hepatomas, inactivates codon recognition we can conclude that hepatoma tRNA₁^{Phe} is not simply derived from the normal tRNA^{Phe} species as an artefact due to partial excision of the Y base during isolation of hepatoma tRNA. tRNA₁^{Phe} can function in codon recognition because, although it lacks the Y base, it presumably has another base in the position adjacent to the 3' side of its anticodon. From our present data it is not possible to decide whether the tRNA₁^{Phe} species represents the expression of a separate tRNA gene (perhaps a foetal tRNA gene¹⁵) in certain hepatomas or only an immature form of tRNA₂^{Phe} resulting from a failure to complete the synthesis of Y base from its precursor guanosine molecule^{11,12}. Nucleotide sequence studies should resolve this question and these are in progress.

We thank Mrs Vesna Ivanovic for assistance and Dr Harold P. Morris for providing the original stock of hepatoma 7777. This work was supported in part by The Leukemia Society of America and a United States Public Health Service Research Grant.

Primary structure and sidechain interactions of PFL filamentous bacterial virus coat protein

Two structural classes of filamentous bacterial viruses have been identified on the basis of their X-ray diffraction patterns. The class I structure¹ is found for the fd, If1 and IKe strains, while the class II structure² is found for the Pf1 and Xf strains. The two classes differ in the number of protein subunits per turn in the virus helix (4.5 units per turn for class I and 4.4 for class II, with ~ 15 Å pitch), and in the fact that a periodic perturbation of the structure is observed for class I but not for class II. The major coat protein, which comprises about 99% of the virus coat, is largely α -helical^{3,4} with a molecular weight of about 5,000 for all strains investigated². The sequence of the fd coat protein^{4,5} is known. It is 50 residues long, with an acidic N-terminal region, a hydrophobic middle region and a basic C-terminal region. To facilitate the detailed analysis of the class II structure, and to investigate the possibility that the structural differences between class I and class II arise from differences in the coat protein, we have determined the sequence of Pf1 coat protein. This is the first system for which a molecular model of a structural protein has been described in sufficient detail to permit study of the bonding specificity between proteins. Since the α helix is a universal structure, study of the interactions between α helices can be of central importance in many unrelated systems. We have found that α helices are arranged in the virion so that hydrophobic sidechains on each protein subunit can fit into the space between sidechains on neighbouring subunits.

Pf1 virus was grown and purified as described previously², and the coat protein was purified from the virion by phenol extraction and methanol precipitation⁴.

The coat protein of Pf1 consists of 46 amino acid residues. Its amino acid composition is somewhat unusual in that it lacks proline, cysteine, histidine and tryptophan. The sequence was determined by several methods. The first 39 residues from the N terminus were established by automatic sequencing using the JOEL-JAS 47K sequence analyser. The C-terminal sequence was shown to be -Arg-Lys-Ala by carboxypeptidase A and B digestion. Treatment of Pf1 coat protein with cyanogen bromide gave three fragments containing 23, 19 and 4 residues which were separated by gel filtration and paper electrophoresis. Amino acid analysis showed that these fragments accounted for the entire coat protein. It also facilitated the assignment of the 19-residue fragment as the N terminus and the 4-residue fragment as the C terminus. The structure of the 23-residue fragment was determined by automatic sequencing. These results were confirmed by the isolation and sequencing of the five chymotryptic peptides obtained from a digest of the succinylated protein. The results of these determinations showing the location of the cyanogen bromide fragments and chymotryptic peptides, and sequences established by Edman degradation and carboxypeptidase digestion, are shown in Fig 1.

The coat protein sequence of Pf1 is compared with that of fd in Fig 2. The sequences are aligned on the basis of similarities in the predicted secondary structure. With this alignment, the average minimum base change per codon⁶ required to go from the Pf1 to the fd sequence would be 1.24. Although fd and Pf1 might be related by convergent evolution, this seems unlikely in view of the complexity of the virions. If the two viruses are related by divergent evolution, a time scale for evolution⁷ calibrated on minimum base change per codon suggests that the two viruses would share a common ancestor in existence about 3×10^9 yr ago. The similarity² between the A proteins

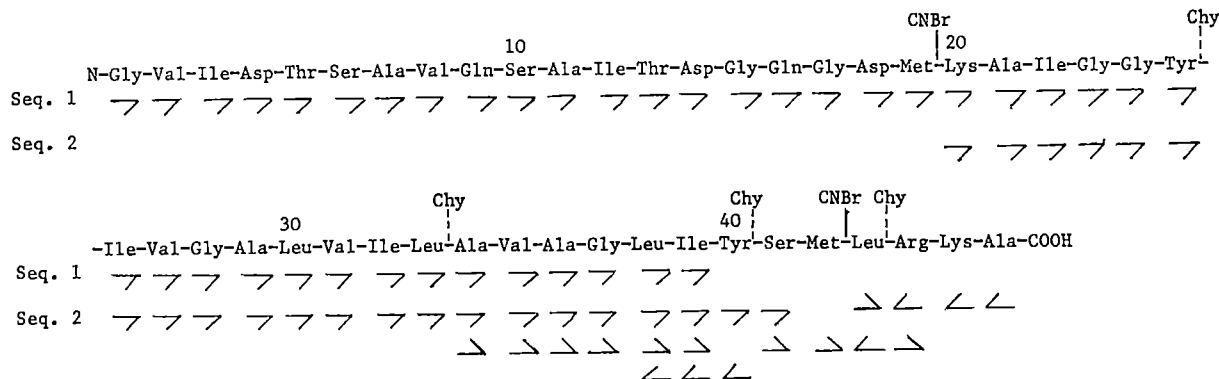

Fig 1 Determination of the Pf1 coat protein sequence. Seq 1 and seq 2 (→) are determinations using the JOEL-JAS 47K sequence analyser, (↔) are sequences determined by dansyl-Edman degradation, and (←) are sequences established by carboxypeptidase A and B digestion. CNBr and Chy indicate sites of cleavage by cyanogen bromide and chymotrypsin, respectively.

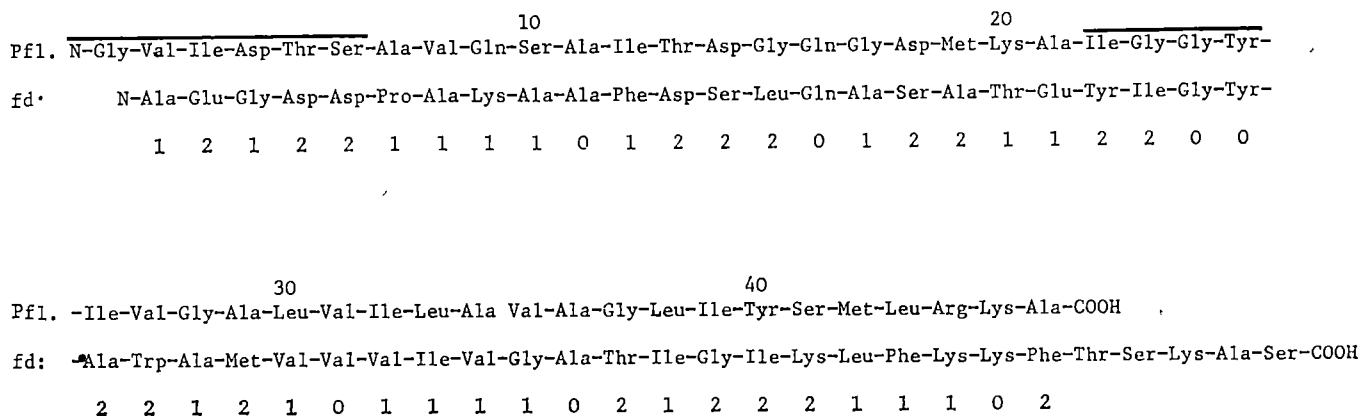

Fig 2 Comparison of the Pf1 and fd coat protein sequences. Sequences were aligned on the basis of the positions of non-helical residues and the positions of basic residues at the C terminus. The regions identified by bars have low probability of α helix⁹. The numbers in the third row indicate the minimum base change per codon required to give the observed amino acid change, taken from Table 2 of ref 6.

of the two highly divergent strains would then suggest that this protein has some fundamental and immutable function in the life cycle of the virus⁸

Spectroscopic measurements on fd^{3,4} and Pf1 (R L W and

L A Day, in preparation) show that more than 90% of the residues in the coat protein are in the α -helix conformation. To identify possible non-helical regions, the observed probability of finding residues in α -helical regions (P_α) or β sheet regions (P_β) was used to predict the secondary structure from the sequence⁹. The only two regions of four or more residues with average P_α less than one are indicated by bars in Fig 2. The Pro-6 of fd is included at the N terminus of the α -helical region as observed for several structures⁹. Residues 22–25 of

Fig 3 Ball-and-stick representation of α carbon atoms in neighbouring α helices of the current Pf1 model. Atoms are projected on to a plane parallel to the z axis of the virion, to give a view similar to that shown in Fig 5 of ref 10. Numbers indicate residues. The three subunits illustrate the contacts between any subunit (0) and the subunits five units (-5) and nine units (-9) down the virus helix.

Fig 4 Surface lattice of the Pf1 α -helical coat protein. Positions of residues are projected on to a cylinder which is opened flat and viewed from the outside. Hydrophobic residues or residues involved in van der Waals' contacts are circled (the classification of glutamine, serine and tyrosine as hydrophobic is discussed in ref 14). Dashed lines indicate the lines of contact between the 0 and -5 molecules, and solid lines indicate the lines of contact between the 0 and -9 molecules. In each case the lower line represents the line of contact on the 0 molecule, and the upper line represents the contacts on the other molecule (see also Fig 3).

* Position I and position II refer to the different kinds of sidechain contact on the left and right of the line of contact, as defined in ref 14. A residue in position I is 3 residues on the N-terminal side and 4 residues on the C-terminal side of a residue in position II.

† ●, Van der Waals' contact between β - and γ - or δ -carbons and hydrogens, not involving charged residues. ○, Van der Waals' contact between β - and γ - or δ -carbons and hydrogens, involving charged residues. —, no β - to γ - or δ -carbon and hydrogen van der Waals' contact. Taken from Figs 8 and 9 of ref 14.

† Distance between β -carbons. Where one of the residues involved in the contact is glycine (indicated by G), the distance is given to the position that would be occupied by β -carbon if the residue were alanine.

Pf1 (21-24 of fd) could represent a bend in an α helix involving breakage of a few hydrogen bonds, rather than a drastic disruption of the helix. The non-helical region at the N terminus is sufficient to account for the observed fraction of non-helical residues. The N terminus is probably at the outside surface of the virion¹⁰. This non-helical region is reminiscent of the globular head group at the N terminus¹¹ of the α -helical myosin molecule, situated at the outside surface of myosin filaments in muscle.

For study of sidechain interactions, the Pf1 coat protein can be represented as a 46-residue rod of α helix. The placement of the coat protein rods in the virion¹⁰ shows that there are two main types of interaction between proteins from each protein to the proteins originating 5 and 9 units down the ~ 15 Å virus helix (Fig. 3). The axes of neighbouring α helices make an angle of 9-12° with each other over most of the 40 Å interaction region¹⁰. Analysis of knobs-into-holes interaction of sidechains on infinitely long idealised α helices shows that the sidechains of one helix can fit into the space between sidechains on its neighbour only if the two helices wind around one another with an angle of 20° between the helix axes¹². The region of interaction between Pf1 coat proteins, however, is short enough to permit knobs-into-holes packing over the whole of the interaction region in spite of the small crossing angle.

The remarkable resistance¹³ of filamentous bacterial viruses to extremes of pH suggests that the α helices are held together by hydrophobic bonds rather than salt bridges or hydrogen bonds. The details of sidechain interactions were therefore examined using the principles of van der Waals' interaction developed for tropomyosin coiled-coils¹⁴. Sidechain interactions were explored for several rotations of the α -helix subunit about its own axis (all subunits were assumed to have the same orientation). One orientation was clearly better than all others tried (Fig. 4). Most hydrophobic residues (24 out of 32) are directly involved in interactions with residues on neighbouring α helices (this number includes Val-35 and Met-42, residues that are involved in the shorter interaction region between the 0 and the -14 subunits). Not only the general hydrophobicity of the residues but also the detailed stereochemistry of the interactions is acceptable with this orientation (Table 1). Ten out of the sixteen interactions are of the most favourable type¹⁴, involving van der Waals' contact between β - and γ - or δ -carbons and hydrogens, of these only two involve charged sidechains. The remaining six interactions are of a type that would not permit van der Waals' attraction for regularly aligned α helices, but three of these are in the possible non-helical regions (residues 1-6). For two more, the bending of the α helix in the Pf1 model causes β -carbons to approach to within less than 5 Å of each other, so that van der Waals' attraction might even be possible at these positions.

The coat proteins of both class II viruses, Xf¹⁵ and P1, are about 10% smaller than those of the class I viruses fd and If1 (51 residues: Y N, unpublished). The perturbation observed in

the structure of class I but not class II virions might be due to the additional four or five residues at the C-terminal end of the coat protein. The C-terminal ends are presumed to be in the interior of the virus shell¹⁰, so that additional material here could lead to interference and thus to a structural perturbation.

The model-building approach to molecular structure requires that any acceptable model not only gives a calculated Fourier transform sufficiently close to the observed X-ray data, but also makes stereochemical sense at a level beyond the resolution of the X-ray data. The model-building approach has in the past been restricted to structures made of covalently bonded subunits, such as helical polypeptides or polynucleotides. But this approach can also be useful for the filamentous bacterial viruses, even though the subunits are not covalently linked, because of the knowledge available about internal stereochemistry of α helices and about van der Waals' interactions between α helices. The analysis of sidechain interactions presented here indicates that the model proposed for the Pf1 virion is indeed stereochemically acceptable.

Vaccination of non-human primates against malignant lymphoma

HERPESVIRUSES are the most important candidates for human cancer agents. The Epstein-Barr virus (EBV) in particular is suspected of being the causal agent in Burkitt's lymphoma and nasopharyngeal carcinoma¹. Immunological principles, well understood from vaccine prophylaxis of viral diseases, provide the potential for the eventual control of herpesvirus-induced neoplasia. The development of safe and efficient cancer vaccines with the human candidate herpesviruses is, however, difficult, as there are no reliable *in vitro* or experimental animal methods for detecting oncogenic potential in preparations which might be applicable to the human subject. We are studying the problems of herpesvirus cancer vaccines in non-human primates. Two members of the herpesvirus family, *H saimiri* (HVS) and *H ateles* (HVA), induce malignant lymphoma and leukemia in several New World monkey species^{2,3}. HVS-induced lymphoma in cotton topped (CT) marmoset monkeys (*Saguinus oedipus*) has been used in this study as all monkeys inoculated with HVS regularly develop malignant lymphoma within two months^{4,5}. This investigation describes the effect of a killed herpesvirus cancer vaccine in protecting non-human primates against malignant lymphoma.

in owl monkey kidney (OMK) cell cultures with a constant serum dilution (1/5) and varying tenfold virus dilutions according to standard techniques⁷. Three of the actively immunised monkeys (A, B and C) have been under observation for more than a year (581 days). The serum antibodies appeared 3-4 weeks after the first immunisation and reached their maximal titres 2-3 weeks later. The antibody titres slowly dropped during the first year and rose again after a booster injection (Table 1).

Out of the 42 immunised monkeys 22 were challenged with HVS. The stock virus, grown in OMK cells⁸, was passed through a Millipore membrane filter (450 nm) and serial tenfold dilutions of the filtrate were prepared. Aliquots (1 ml) of each dilution were injected intramuscularly into immunised monkeys and also into non-immunised control monkeys. The infectivity titre (TCID₅₀) of the virus dilutions was determined in parallel in OMK cells.

In the first experiment three immunised monkeys were challenged with the 10⁻³ dilution of the stock virus and three monkeys with the 10⁻⁴ dilution. The TCID₅₀ of the 10⁻³ dilution was 10 and corresponded to 18 LD₅₀ calculated according to the method of Reed and Muench. All of the vaccinated monkeys survived without any signs of disease and have now been under observation for 337 days. All of the non-immunised monkeys which received the 10⁻³ dilution and two out of three control monkeys which were inoculated with the 10⁻⁴ dilution died of malignant lymphoma 34-51 d after inoculation, indicated by gross pathology and histopathology (Table 2). The tumour-bearing animals carried the HVS genome in their peripheral white blood cells as shown by cocultivation with OMK cells and they developed serum antibodies against HVS. In contrast to the tumour-bearing control monkeys, the HVS could not be extracted from fresh peripheral white blood cells of the vaccinated monkeys by cocultivation methods.

*Neutralisation indices

†Titres of complement fixing antibodies

c, Serum had anticomplementary activity

‡The monkey received a booster injection of killed HVS

The killed vaccine was prepared by inactivation of HVS with heat (56°C for 4 h) and formaldehyde (100 γ ml⁻¹ for 6 days) as previously described⁶. The HVS-specific antigenicity of the killed vaccines was determined by the complement fixation (CF) test according to standard procedures⁷. An HVS-specific antiserum from an owl monkey latently infected with HVS⁸ was used in the CF test. The CF titres of the vaccines ranged between 1/32 and 1/64. Before use, the vaccines were adsorbed on to Aluminiumhydroxydgel (10% v/v of a 3% solution, Behringwerke, Marburg, West Germany) as adjuvant. For immunisation four to six intramuscular inoculations of the vaccine were given to each monkey within 4-10 weeks, starting with 1.0 ml vaccine for the first inoculation and 0.5 ml for each of the subsequent inoculations. The 42 CT marmoset monkeys actively immunised with the vaccine remained clinically well and developed high titres of neutralising and CF antibodies against HVS. The neutralisation tests were performed

In the second challenge experiment a higher dosage of HVS was used. A 10⁻² dilution of the stock virus was given to four vaccinated monkeys and another four vaccinated monkeys received a 10⁻³ dilution. The 10⁻² dilution contained 100 TCID₅₀ which corresponded to 215 LD₅₀. All of the challenged monkeys were resistant to infection with HVS (Table 2) and have now been under observation for 206 days without any indication of tumour development. All of the non-vaccinated controls which received the 10⁻³ dilution and three out of four monkeys which received the 10⁻⁴ dilution died of malignant lymphoma within 36-52 d of inoculation.

In the third experiment the 10⁻² and 10⁻³ dilutions of the stock virus were again used to challenge four vaccinated monkeys in each group. Since the first and second experiment had shown that 1 TCID₅₀ of HVS corresponded to about 2 LD₅₀, the titration of the inocula in non-vaccinated control monkeys was omitted. Both groups of monkeys in this third

experiment which were challenged with 9 or 90 TCID₅₀, corresponding to about 18 or 180 LD₅₀, have now been under observation for 165 d. The monkeys have remained clinically well and do not show any signs of tumour development (Table 2).

These experiments clearly demonstrate that a malignant tumour in non-human primates can be prevented by a vaccine. The neoplasia investigated is a malignant lymphoproliferative disease induced by inoculation of cell-free HVS into CT marmoset monkeys under laboratory conditions. Under natural conditions HVS appears to be transmitted horizontally, similar to other herpesviruses which have been associated with neoplasia. The prophylaxis of the malignancy was achieved with a killed vaccine prepared from the oncogenic HVS by inactivation. The vaccine proved to be safe and efficient as yet. All vaccinated monkeys developed high titres of humoral antibodies against HVS and remained clinically well. The immunity against HVS can be broken, however, by very high challenge dosages, such as 10^{3.8} TCID₅₀ of HVS⁶. Experiments in progress indicate that the vaccinated monkeys are not resistant to malignancy caused by tumour cell transplantation. The tumour prophylaxis with the killed HVS vaccine and the finding that the TCID₅₀ of HVS correlated very well with the LD₅₀ of HVS support the concept that HVS is indeed the aetiological agent of malignant lymphoma in monkeys. The preparation of killed vaccines may be advantageous with respect to the candidate human cancer herpesviruses since it will be very difficult to exclude oncogenicity of live attenuated vaccines before clinical trials. Recently two groups of investigators showed that EBV-induced lymphoid tumours in *S. oedipus*⁹ and in an owl monkey¹⁰. A killed EBV vaccine may be prepared and tested in non-human primates analogous to the HVS cancer vaccine.

***In vitro* absorption and molecular weight of specific T-cell suppressor factor**

THE lymph node cells of mice rendered unresponsive by the injection of picryl sulphonic acid (PSA) depress the passive transfer of contact sensitivity¹. When the mice are also painted with picryl chloride the lymph node cells produce suppressor factor *in vitro*. This factor depresses the passive transfer of contact sensitivity by immune cells and its production is T-cell dependent². Here we show that suppressor factor(s) has a molecular weight ~50,000 and that it is absorbed by and can be eluted from specific antigen in the form of picrylated albumin attached to Sepharose beads.

Suppressor factor was prepared by injecting CBA mice intravenously with 5 mg neutralised PSA (BDH). The abdomen and forepaws were painted with 0.15 ml 7% picryl chloride (PCI) in ethanol 5 d later. The draining lymph nodes were taken the next day and live cells (1.2×10^7 ml⁻¹) were incubated in Eagle's minimal essential medium (Difco) containing 10% foetal calf serum, penicillin, streptomycin and glutamine for 48 h. The gas phase was O₂ 7%, N₂ 83%, CO₂ 10%. The supernatants were collected by centrifugation (300g, 10 min) followed by top speed on a bench centrifuge for 30 min. Control (inactive) supernatants were prepared from mice which were painted with PCI but had not received PSA.

In the direct test² the fractions were tested for their ability to inhibit the passive transfer of contact sensitivity to PCI by incubating immune cells in them (Table 1). They were also tested in the indirect test² which is based on the fact that normal peritoneal exudate (PE) cells incubated in suppressor supernatant inhibit the passive transfer of contact sensitivity by immune cells. Five day oil-induced (light liquid paraffin)-PE cells were incubated with fractions (1.2×10^7 ml⁻¹, 1 h, 37°C).

Table 1 Absorption and elution of suppressor factor from picrylated and 'oxazolinated' albumin on Sepharose beads

	Increment of ear thickness \pm s.d. at	
	24 h	48 h
Control (inactive) supernatant	4.1 \pm 0.65	5.2 \pm 0.68
Suppressor supernatant	1.8 \pm 0.51	2.3 \pm 0.49
Suppressor factor absorbed with Pic beads*	4.0 \pm 0.62	5.0 \pm 0.78
Suppressor factor absorbed with Ox beads*	2.3 \pm 0.59	2.8 \pm 0.58
Elate from Pic beads	2.2 \pm 0.84	2.9 \pm 0.72
Elate from Ox beads	3.9 \pm 0.47	4.6 \pm 0.50
Control supernatant eluted from Pic beads	3.6 \pm 0.56	4.8 \pm 0.79
Negative control (non-specific swelling)	1.5 \pm 0.54	1.6 \pm 0.30

The supernatants were absorbed three times by picrylated (Pic) or oxazolinated (Ox) Sepharose beads. The supernatants and eluates were assessed in the direct test by incubation with 4 d PCI immune cells (5×10^7 ml $^{-1}$, 1 h, 37°C). They were washed twice and 4×10^7 cells were injected into each of five recipients. The mice were challenged with 1% PCI in olive oil and passive transfer assessed by the increment of ear thickness. This experiment was repeated on two additional occasions with similar results but the Ox-bead absorptions were not undertaken.

* Bovine serum albumin (1%) beads was coupled to activated sepharose 4B beads at pH 6.2 (ref. 3). Picrylation: 0.1% PSA, pH 9.5, 48 h, room temperature. Oxazolonation: 10 ml beads, 20 ml 0.2 M borate buffer pH 8.4, 0.2 and then 0.3 ml, 5% 4-ethoxymethylene-2-phenyloxazolone (BDH) in ethanol, squirted from a syringe, 18 h. The beads were washed with 0.1% Tween, pH 2.3, 0.2 M glycine-HCl buffer, and PBS.

They were spun down, washed twice and mixed with 4 d immune cells and injected into groups of five mice (4×10^7 immune cells, 1.2×10^7 PE cells per recipient).

In a typical experiment, mice injected with immune cells incubated in tissue culture medium (CS_{100%}) give a mean increment of ear thickness of 4.4 units (10^{-3} cm), after challenge with PCI, while mice which received no cells (CS_{0%}) give a mean increment of 1.4 units. The inhibition caused by a fraction (CS_{exp}) is expressed as percentage inhibition:

$$(CS_{100\%} - CS_{exp}) / (CS_{100\%} - CS_{0\%}) \times 100$$

Figure 1 shows a Sephadex G-100 experiment. The initial suppressor supernatant gave 97% inhibition. Most of the activity in the direct test (87% inhibition) occurred in the fetus area (molecular weight, 48,000) with less activity in the albumin area (molecular weight 67,000). A little activity eluted after fetus (27% inhibition). These results were confirmed in the indirect test which also showed activity eluting after the fetus area.

Fractions from control supernatant were virtually inactive. The only inhibition found in the direct test was 7% in the

albumin area. In the indirect test, 10% inhibition occurred in the albumin area and 3% in the fetus area.

These results were confirmed in six additional gel filtration experiments. Table 2 shows that in the direct test using fractions from a G-200 or G-100 column there was little or no activity in the void volume and the maximal activity was in the fetus area. With G-50 an average of 77% inhibition occurred in the void volume and a mean of 90% with material which

**Fig. 1** Gel filtration of suppressor supernatant on Sephadex G-100

eluted later. The G-50 data suggest that there may be material with a molecular weight below fetus. This may have been missed in the G-100 experiment because of the loss of material which occurs on freeze-drying from dilute solutions.

The indirect test gave the same general pattern of results but the inhibition in the IgG area was greater. These results were confirmed using Amicon filters PM-100, XM-50 and UM-10. The fractions with presumptive molecular weight above 100,000 and below 10,000 were inactive. Material lying between 100,000 and 50,000 daltons gave 66% inhibition while material between 50,000 and 10,000 daltons gave 89% inhibition.

It was concluded that suppressor factor behaved as though it had a molecular weight close to that of fetus (48,000). It is probably polydisperse. It is not clear whether the material with

- a molecular weight in the IgG and IgM area detected in the indirect test is an antibody or antibody-antigen complex or a low molecular weight T-cell product combined with a high molecular weight picrylated protein

The following experiments provide immunochemical evidence for the specificity of suppressor factor and show that it can be specifically absorbed by and eluted from picrylated but not by 'oxazolinated' protein bound to Sepharose beads

Suppressor supernatant (16 ml) was absorbed on to picrylated or oxazolinated beads. For elution the beads used for the first absorption (8 ml) were washed four times in 200 ml ice cold saline and resuspended in 3 ml tissue culture medium with 1% foetal calf serum and heated at 56°C for 30 min. The supernatant was removed and 3 ml of 2 M NaCl added. This was removed after 15 min at room temperature and followed by 0.1 M, pH 2.7 glycylglycine-hydrochloric acid buffer for 15 min. The eluates were dialysed against phosphate buffered saline, pH 7.2, followed by tissue culture medium. Foetal calf serum was added to 5% and the eluate assessed in the direct test.

Table 2 shows that suppressor activity was specifically absorbed by and eluted from picrylated beads. This specific absorption shows that this suppressor factor is not an anti-receptor site factor of the type described by Ramseier⁴. It is not known whether the suppressor factor is a specific T cell product or a complex of the specific T cell product and antigen. In the latter case the molecular weight of the T cell product without antigen is less than about 50,000 daltons and may be much lower.

The suppressor factor described here has a similar molecular weight to the suppressor factors which specifically prevent a tumour rejection (S. Fujimoto, M. Green, and A. H. Sehon, unpublished) and specifically depress the homocytotrophic (presumptive IgE) antibody response⁵. Purification by gel filtration and absorption and elution from antigen opens up the possibility of detailed immunochemical studies.

We wish to thank the Medical Research Council for facilitating this work and the Polish Academy of Science for financial help, and Norton Hadler for technical advice.

Errata

In the article "Stimulation of synaptosomal dopamine synthesis by veratridine" by R. L. Patrick and J. D. Barchas (*Nature*, **250**, 737, 1974) the following corrections are necessary. Paragraph 2, line 6 should read 'fraction has been shown to be associated with the synaptosomal component' and not as printed. In line 4 of the last paragraph 'interact' should read 'intact'. There were also errors in the Tables which, for the sake of clarity, are reprinted in full below.

Table 1 Effect of tetrodotoxin on the veratridine-induced increase in dopamine synthesis

	Dopamine synthesis (nmol h ⁻¹ g ⁻¹)
Controls	9.54 ± 0.53 (12)
Tetrodotoxin	9.50 ± 0.57 (12)
Veratridine	14.7 ± 0.46 (12)*
Tetrodotoxin + veratridine	10.5 ± 0.43 (12)

Aliquots of the striatal P₂ fraction were incubated for 5 min at 37°C either without further additions or in the presence of tetrodotoxin (2 × 10⁻⁷ M) followed either by the simultaneous addition of veratridine (7.5 × 10⁻⁵ M) plus L-1-¹⁴C-tyrosine (1 × 10⁻⁵ M) or by the addition of tyrosine alone, and incubated for an additional 5 min. The apparent rate of synthesis was calculated by dividing the d.p.m. of product formed per hour per gram of original tissue by the specific activity of the tyrosine added to the medium. The normal incubation medium had the following composition: NaCl, 125 mM; KCl, 5 mM; CaCl₂, 1 mM; MgCl₂, 1 mM; glucose, 10 mM; ascorbic acid, 1 mM (made fresh daily), and Tris HCl, 50 mM, pH 7.4. Values represent the mean ± s.e.m. The number of observations is in parentheses.

*P < 0.001 controls, P < 0.001 tetrodotoxin plus veratridine (t test)

Table 2 Calcium dependence of the veratridine-induced increase in dopamine synthesis

	+ Ca ²⁺	Dopamine synthesis (nmol h ⁻¹ g ⁻¹) - Ca ²⁺ + EGTA	- Ca ²⁺
Controls	13.8 ± 0.22 (18)	13.8 ± 0.41 (18)	12.8 ± 0.72 (10)
Veratridine	18.1 ± 0.30 (18)*	14.4 ± 0.44 (18)	12.0 ± 0.82 (10)

Aliquots of the striatal P₂ fraction were incubated for 5 min at 37°C either in control medium, Ca²⁺-free medium containing 1 mM EGTA, or simply Ca²⁺-free medium, followed by the simultaneous addition of veratridine (7.5 × 10⁻⁵ M) plus L-1-¹⁴C-tyrosine (1 × 10⁻⁵ M) or by the addition of tyrosine alone, and incubated for an additional 5 min. Values represent the mean ± s.e.m. The number of observations is in parentheses.

*P < 0.001 controls

In the article "Dissociation of EEG and behavioural effects of ethanol provides evidence for a noncholinergic basis of intoxication" by W. R. Klemm (*Nature*, **251**, 234, 1974) the following corrections should be made. In the legend to Fig. 1, the dose of eserine (Fig. 1b) should be 0.2 mg kg⁻¹, and of alcohol (Fig. 1c) should be 2 g kg⁻¹. Likewise on page 235, right-hand column, line 27, the dose should be 2 g kg⁻¹.

In the article "Radiocarbon chronology for Seibal, Guatemala" by R. Berger, S. de Atley, R. Protsch and G. R. Willey (*Nature*, **252**, 472, 1974) the first word in line 4, para 1 should read 'stages' and we erroneously gave the address of R. Protsch as Frankfurt am Main, DDR, when in fact it should be West Germany.

reviews

The Social Behaviour of the Bees: A Comparative Study. By Charles D. Michener. Pp. xii+404. (The Belknap Press of Harvard University: Cambridge, Massachusetts, July 1974.) \$25.00.

THE conspicuous social behaviour of bees has undoubtedly been the main reason why they have always stimulated much attention, and continue to do so, with the result that they are kept in the forefront of entomological research. It is indeed a challenging task to attempt to synthesise the accumulated research findings on social bees, and it is one which Professor Michener has ably and brilliantly fulfilled. This book is timely and appropriate and the wealth of recent knowledge gleaned from many sources and many studies is interwoven skilfully around the recurring theme of the origin and evolution of social life to produce a masterly and fascinating exposition. Readers are especially fortunate that Professor Michener's deep and wide knowledge of his subject enables him to put current or fashionable ideas into an objective perspective.

The arrangement of the subject matter of the book into three parts is unusual but effective. Part I is a useful introduction for those unfamiliar with bees. It includes background material about their development, discussion of the features that seem to be involved especially in social behaviour (for example, mouthparts, sting, pollen collecting apparatus and various glands), evolution and classification, and the terminology commonly used.

Bees are unique among social insects in exhibiting a broad spectrum of stages illustrating the evolution of social behaviour. In Part II—the largest part of the book—the types and levels of bee societies and the origins and growth of aggregations and colonies are discussed. Several topics are then taken in turn and for each topic bees exhibiting different stages of social organisation are considered. These topics include the nest and its contents, control of the physical environment within the nest, control of male and female production and sex ratio, caste differences and caste determination, division of labour, colony multiplication, orientation to the nest and food sources, foraging behaviour and communication and colony defence.

I found the chapters on the social

Stephen Dalton

Social organisation of bees

significance of the nest and its contents and on the handling and transfer of materials within the nest to be the most absorbing because from these two chapters one obtains a vivid evolutionary picture of how a series of relatively simple stimuli, and the flow of food and pheromones between the members of a colony, can result in the co-ordinated activities of many thousands of individuals. These subjects have recently undergone intensive research and it is only by a complete and proper understanding of them that we will be able to discover the reasons for population fluctuations and changes in foraging intensity. Such an understanding will, incidentally, help us to use the honeybee more effectively both as a producer of honey and as a pollinator of crops. For example, Professor Michener's initial discovery that the activity of each halictine bee diminishes with an increase in the size of the colony concerned has been extended to other social bees, including the honeybee, for which it has important practical applications. Readers will, however, be fascinated equally by the chapters on caste determination—a subject that is currently attracting much attention—and on the dance language of bees, the interpretation of which has recently been the subject of a controversy that is summarised skilfully and objectively.

The last chapter in Part II, which is devoted exclusively to the origin and evolution of social behaviour, is in many ways the hub of the book. There, Professor Michener discusses the prerequisites necessary for a species to evolve a social behaviour and the

characteristics associated with different levels of social organisation. He also considers how selection could operate to establish various social attributes paying particular attention to kin selection and the role of altruism.

Part III entitled "Natural History" is an account of the locations, architecture and contents of nests, and a discussion of the general biology, life history, behaviour and social status of each of the main groups of social bees, including the semi-social and eusocial halictine bees, euglossine bees, allodopine bees, bumblebees and the stingless and true honeybees. Professor Michener recommends that readers seeking information on a particular group of social bees should read the relevant section of Part III before checking the index for material in Part I and II. Because of the efficient index this system works well in practice, but Part III could, in effect, have preceded Part II. The book is illustrated liberally; the diagrammatic sketches of nest structure and architecture are especially worthy of attention. There is a glossary, and a useful appendix aimed at relating the up-to-date nomenclature used in the book to any older nomenclature the reader may encounter. The book is documented throughout: half of the 700 or so references were published during the past decade and over 80% during the past two decades, reflecting the current interest and progress in the subject.

The entomologist who studies social insects may well find that other insects are somewhat dull by comparison. Readers of Professor Michener's book will appreciate why. **John B. Free**

Viruses

Comprehensive Virology. Edited by Heinz Fraenkel-Conrat and Robert R. Wagner. Pp. x+191. (Plenum Press: New York and London, 1974.) \$15.00.

VOLUME 1 of this series is unquestionably comprehensive. The *Descriptive Catalogue of Viruses* lists nearly 500 animal viruses, from "Acado" to "Zika", some 350 plant viruses from "Amapari virus (renavirus)" to three viruses of protists from "A" to "ZS", (both bacteriophages of *Escherichia coli*). The descriptions range from purely taxonomic designations — "Amapari virus (arenavirus)" to three pages of detail on tobacco mosaic virus. There are a few errors, a few eccentricities, (an extra 'i' in -viridae throughout), a few omissions (such as the ephemeral fever virus), and perhaps a few mycoplasmas still masquerading as plant viruses. This is, nevertheless, a unique compilation. **J. S. Porterfield**

Choosing and chancing

Our Future Inheritance: Choice or Chance? A Study by A British Association Working Party. Pp. ix+141+4 plates. (Oxford University: London, October 1974.) £4.00 boards; £1.25 paper.

It has become axiomatic that science, the acquisition of knowledge, should be expected to increase the health, wealth and happiness of mankind. That would seem to apply especially to the results of studies on the various complex processes concerning reproduction, whether they be directed at stimulating fertility or curbing prolificacy.

The British Association and its panel of experts are to be congratulated on this publication. The book, though recognising the benefits accruing from advances in biomedical techniques in the field of reproduction and genetics, urges, quite rightly, that a close watch be kept on possible dangers that could arise from their application to disorders in man.

The terms AID, fertility drug, organ-transplant, test-tube baby, and genetic engineering have all become quite commonplace as a result of popular reporting in the media. The methods and results of the scientific procedures associated with these terms are presented accurately. More important is the awareness that is created of the grave consequences that could follow man's deliberate manipulation and possible interference with his own genes, gametes or gonads. The germ cells, which, strictly speaking, are not vital to the individual are well known for their greater sensitivity to environ-

mental and other changes than are somatic cells.

It is intended that the book should be widely read and it deserves to reach all classes of professional and lay people so that the significance of advances in biological sciences, and their application to human medicine, can be fully realised.

The manner of presentation of a scientific subject in a form acceptable to the lay public is problematical but the authors/editors have overcome skilfully a very difficult situation. I get the impression that the book has been presented in such a way that if members of the public who are scientifically uninformed wish to read and understand it they would obtain all that was needed from the first chapter ('Bio-medical advances: a mixed blessing?') and the last chapter ('Social concern and biological advances'). It is regrettable that those two chapters cannot be made more freely available for all to read and enjoy. The intervening chapters contain details about various technical advances and will require a fair understanding of the relevant subjects if they are to have any lasting effect and impression.

The case-bound volume is well produced and contains a useful index.

I. W. Rowlands

Exercise and sport

Science and Medicine of Exercise and Sport. Edited by Warren R. Johnson and E. R. Buskirk. Pp. 486. (Harper and Row: New York and London, 1973.) £10.00.

THIS volume is a collection of 33 chapters compiled by 40 different authors, linked by a common interest in the physiological and medical aspects of sport and exercise. Each contribution is a short review article; the subjects dealt with range from basic biochemical features of contracting muscle to the effects of exercise on the mental state of psychiatric patients. At the end of each chapter is a list of cited references. There is, however, no general index for the whole book.

I found it difficult to determine for whom the text was intended. The general non-scientific reader would find it incomprehensible. A scientist with no specialised knowledge of the subject would find the format difficult reading: it is fragmented, it lacks a theme, and it is therefore indigestible. Perhaps it would be of interest and use to a student writing a dissertation on the scientific and medical aspects of exercise and sport. Its place would therefore seem to be more appropriate to the shelves of a reference library than to a private bookcase.

R. Y. Calne

Rhythm book never swings

Biological Clocks in Marine Organisms: The Control of Physiological and Behavioural Tidal Rhythms. By J. D. Palmer. Pp. x+173. (Wiley: New York and London, June 1974.) £6.85.

In this book the author attempts to bring the problems and fascinations of the study of biological clocks in marine organisms before a wide audience. The book is, in fact, an expansion of the author's recent review in the journal *Biological Reviews* and is the first of its kind.

It is about the way in which various activities of a whole range of marine animals are instigated and controlled by some facet of the rhythm of the tides. An essential aim of any animal is to maximise the efficiency of, for example, its feeding so that it takes the greatest advantage of food when available. Thus, an intertidal animal which is quiescent when the tide is out undergoes changes when the tide is due to cover it so that it is absolutely ready to feed when water covers it. This preparatory behaviour persists for a period when the animal is removed to a laboratory, demonstrating its innate character. The description of a variety of phenomena of this kind, and the mechanisms behind them, form the substance of this book.

To be completely successful in attracting a wide audience requires subject matter of considerable fascination, a style of writing which is both easily comprehensible and stimulating, and illustrations of high quality. In order to attract future researchers the gaps in present knowledge require emphasis, as do promising lines of research. Unfortunately, although some of these ideals are approached quite closely in some respects the book seems to fall short of its target.

The book is quite comprehensive and incorporates almost all of the significant literature on the subject. It is very well illustrated and the style is generally clear once technical terms are mastered. A very good feature is the summary at the end of each chapter, and the bibliography is of value to the non-specialist.

In spite of that and the obvious expertise of the author, however, I was not greatly stimulated by his treatment of the available material, which seemed rather mundane. I feel that although the general reader is likely to be attracted by the subject he will not be altogether attracted by its presentation; and whether any potential researcher would be fired with enthusiasm is debatable. Dr Palmer does point out the gaps in current knowledge but he never makes one feel that life would

"Circle Limit IV (Heaven and Hell)", a woodcut by Maurits C. Escher. Devils and angels alternate repeatedly and compete for attention. From *Image, Object, and Illusion*. (Readings from *Scientific American*.) Introductions by Richard Held. Pp. 137+155 illustrations. (Freeman: San Francisco and London, 1974.) Cloth, \$8.00; paper, \$4.50.

be incomplete without further knowledge of this or that phenomenon.

The book is undoubtedly a very useful contribution to literature and should be in every biology department's library but its contribution lies in its value as a storehouse of information rather than as a source of inspiration. Its price will probably mean that few other than libraries will buy it.

R. H. Emson

Pain

Recent Advances on Pain. Edited by John J. Bonica, P. Procacci, and C. A. Pagni. Pp. xv+373. (Charles C. Thomas: Springfield, 1974.) \$19.75.

THIS excellent book contains the proceedings of a symposium on the pathophysiology and clinical aspects of pain held in Florence in April 1972. The contributors were eminent men, representing various specialties, from Italy, Switzerland, North America and the United Kingdom.

The main message of the symposium is reflected by its broad coverage—namely, that for both the study of pain and its clinical management a multidisciplinary approach is needed. The subject matter included the neurophysiology of pain, endogenous pain-producing substances, analgesic blocks

and surgery for the relief of pain, pain threshold measurements in man, and operant conditioning for chronic pain. In addition, there is a paper by Professor Bonica on the organisation and function of a pain clinic.

This list, although giving some idea of the scope of this book, does not do justice to the vast amount of information it contains. For those interested in migraine there is a fascinating contribution by Professor Sicuteri, and there are some thoughts on the roles of acupuncture, radiostimulators and inhibitory mechanisms in the relief of pain.

In order that the fruits of many years of research undertaken by the contributors be disseminated as widely as possible this book should be read not only by those whose research is directed towards the study of pain but also by those who are in any way connected with the relief of suffering.

The editing of a book of this kind must be a vast undertaking; none the less, it is a pity that there are so many errors. Apart from spelling mistakes and what seem to be mistakes arising from misread handwriting, it is strange that there are 65 references at the end of Chapter VIII when only nine are mentioned in the text.

Few jobs, but plenty of job security

THE graph on our cover this week encapsulates perhaps the greatest problem confronting British universities at present—that of replacing staff.

For every year since 1960 we looked at the classified advertisement section of *Nature* for the first issue in May and the first issue in November. Any British university post of the level of lecturer or above scored one; temporary posts at the lecturer level (there were very few) scored half. The vertical axis therefore represents, roughly, a measure of the long term openings in science in British universities. The graph could be criticised, no doubt, in all sorts of ways as an inadequate sample but the message is clear. Universities have largely stopped hiring, or 1974 contained a statistical fluctuation, or *Nature* has been abandoned as a medium for advertising university posts (British universities generally advertise in two different places). The last proposition was easy to dispatch: nowhere else is there a boom in university advertisements. Statistical fluctuations were ruled out by looking at a larger sample for 1974. So there just aren't the jobs available.

The peak in the mid-1960s, the other salient feature, arose, of course, from the rapid university expansion at that time; indeed in doing a numerical analysis we frequently had difficulty in deciding how many posts were being offered when a university announced that 'several positions are available'!

The policy that university administrations have adopted in the past year, during which severe financial stringency has dictated a widespread freeze in hirings, has been to treat

individual posts which have fallen vacant on their respective merits, and some have said that a year or two of straitened circumstances might positively do good. This is untrue for two reasons. First, when a system with such a high job security ceases to operate normally it works to the detriment of the bright young man trying to move from contract-based employment to a more stable career. Disruption of his job prospects during the most intellectually fertile period of his life represents a tragic waste of education and talent. Second, just as bad news on employment in the chemical industry a few years ago rapidly had an impact on the image of chemistry in schools, it cannot be long before the failure to fill university posts begins to impress students at all levels with a belief that the academic life is being downgraded in national priorities, and that they should not set their sights in that direction. Even if this were a good thing, it is most undesirable that the control should come from external influences rather than from genuine policy decisions made after rational discussion.

It is unlikely that the brakes will be released from universities in the near future; the government doubtless has many other demands on its money which it perceives as more deserving than the universities. In that case, now is the time for universities to respond to the crisis in an imaginative way. Industry, confronted with a constant budget, would find ways of persuading senior or unproductive staff to leave—and it is often possible to do this without any great loss of human dignity. Tenure is both a blessing and a curse to the university system; might not the golden handshake alleviate some of the curse?

Unsuitable for children

PROFESSOR Eric Laithwaite did not, as was widely predicted, quite urge his audience of schoolchildren at the Royal Institution Christmas Lectures (and the several hundred thousand television viewers) to regard Newton's laws as open to some fairly fundamental doubts. He did not say that he had found a way of counteracting gravity. What he did, however, in the course of his six lectures, was in a way more damaging to the education of young scientists; he mixed parlour tricks with complicated machines, he chose to enlist the mystified children on his side in a battle with conventional scientists—'abominable no-men' as he called some of them—and, worst of all, he emphasised experimentation to the almost complete exclusion of explanation.

The scene was as it ever had been—a lecture hall full of well groomed children on their best behaviour. One wondered idly if there were still nannies, governesses and footmen waiting outside in carriages. The audience was prepared to applaud dutifully the most trivial thing. And the experiments—well they can never have been bettered for ingenuity and visual impact.

But science demands rational explanations. It is simply no good demonstrating at length the celebrated mirror problem (if right becomes left, why doesn't top become bottom?) without going to equal pains to put in children's minds at least some sort of answer. It is no good demonstrating a motor that reverses direction when the voltage

is increased without saying why. And it is positively harmful to venture into the world of gyroscopes, a confusing world for many a competent scientist, without a clear understanding of the rather well known laws of angular motion, an extensive reading of the not inconsiderable nineteenth century literature on gyroscopes and tops and an ability to impart the textbook explanation lucidly. The theory is indeed dry and unattractive; all the more challenge, then, to get it right and still hold your audience. Professor Laithwaite chose, instead, to present the understanding of gyroscopic motion as something which had been languishing for more than a hundred years and which scientists as a whole had chosen both to ignore and to suppress questions on.

One example of the misleadingness of demonstration must suffice. A gyroscope slowly precessing on an 'Eiffel tower' seems to experience no centrifugal force, said Laithwaite, otherwise surely the tower would slide, which it didn't do even when the base was on ice, a surface with a very low coefficient of friction. But not low enough. The centrifugal term is sufficiently much smaller than the normal reaction from the weight of the gyroscope (perhaps one hundredth) that sliding requires an even more slippery surface than ice.

These lectures, said Professor Laithwaite, were not the time nor the place to go into the mathematics; but if not, it was neither the time to launch ideas which could only be criticised by mathematical analysis. □

Between combine harvester and ribosome

An Agricultural Research Council/Medical Research Council committee has recently produced a report on food and nutrition research. John Rivers of the Nuffield Institute of Comparative Medicine, London examines its significance.

PERIODICALLY, action by government committees and individuals in this country has resulted in the science of nutrition being rescued from its characteristic doldrums and becoming a national priority. A government inquiry into the physique of recruits for the Boer War got the subject moving in the first place, and later action by people like Lord Boyd-Orr and Sir Jack Drummond gave a new impetus to its growth. These efforts were successful not least because of the military importance of a healthy population. Since 1945, nutrition in the UK has been neither of military importance nor Nobel Prize ranking. It has lost much Research Council support and the standard of the subject and its workers has declined.

The report* of the committee under Professor A. Neuberger is the latest attempt to enumerate nutritional priorities and halt that decline. It examines not only the nutritional status of Britain, but the state of our nutritional knowledge and recommends guidelines for the development of the subject until the end of the century. The strategy adopted is praiseworthy. Priority, it is argued, must be given to "areas of special importance or urgency". Three such are identified—the maintenance and safety of our food supply, the role of nutrition in diseases of complex or uncertain origin, and the extension of our knowledge of the metabolism of nutrients.

Professor Neuberger's committee were asked to prepare a report for both the Agricultural Research Council (ARC) and the Medical Research Council (MRC), an event which is in itself a milestone. The secretaries of the councils welcome it "as a basis for discussion both within the councils and in the wider scientific community preparatory to the consideration of policy". So far the wider scientific community seems, publicly at least, to have been somewhat muted in its discussion. There is therefore the real

possibility that the Neuberger report could, without challenge, become the policy document. This would be a pity, because, despite all its outstanding qualities, the report is a markedly flawed document. The committee has managed to outline graphically some of the priorities of nutrition, but they have remained oblivious of others. The net result is a report which could set back the overall subject by 25 years.

The bulk of the report is a detailed summary of the present state of knowledge in nutrition. Since something over a gross of experts have been consulted, this makes breathtaking reading. If it were expanded and in parts rewritten it would become a necessary primer in nutrition but, as it is now, its function is obscure. It is too condensed to serve as a text book, it is unreferenced and so of little use as a source book, and it is too high powered to be of use as a guide to civil servants working for the research councils or to trustees of foundations. If it is merely there to impress, it succeeds. Moreover it does so in a way that eloquently illustrates Professor Neuberger's conviction that "the answers to many of the most difficult problems in nutrition are ultimately to be found at the molecular or cellular level of biological organisation".

Sir Harold Himsworth—formerly Secretary of the MRC—held a comparable opinion, and some nutritionists felt then that this was a sadly mistaken and reactionary view. Probably they are even sadder now that Professor Neuberger has revived it. Both Himsworth and Neuberger may have described what the MRC choose to fund, but they are not discussing nutrition. In fact they are describing just what nutrition is not. The subject falls somewhere between the combine harvester and the ribosome, but it is not agricultural engineering nor is it molecular biology. It may draw from both but is identical with neither, and it is to be hoped that research councils are aware of its limits when considering which "nutrition projects" to support.

Human nutrition is about the interaction of Man, men and food. It is both a social and a biological science, the domain of generalists who may have some special expertise but remain generalists. Those answers which can only be found at the molecular level, or indeed the economic level, are answers to problems in molecular biology or economics. Both are im-

portant and both should receive funding, but not with money designated for nutrition research.

The apparent erudition of the Neuberger report tempts one, however, to accept the committee's view. The complexity of its science makes it difficult to argue with its insight. Jehovah's Witnesses quote the Bible for much the same effect, but fortunately Professor Neuberger's sources are neither as infallible nor as all-embracing. The result is a review which is eclectic, not exhaustive. Much of what it says is exciting but what it omits is terrifying. Seventy-five pages, for example, are devoted to physiology and biochemistry but only one to ways of influencing food consumption patterns. Even the stress given to different metabolic problems is difficult to understand, unless the length of the contribution is proportional to the status of the author. So although protein and energy metabolism are elegantly viewed from every angle, and coordinated proposals for research in metabolic aspects of obesity advanced, subjects like sucrose and essential fatty acids (EFA) are hardly mentioned.

Yet sucrose provides 15% of the energy of a UK diet—which is a higher fraction than protein supplies. This is a level of consumption which alarms many nutritionists and can delight nobody except the British Sugar Bureau. For some reason the nutrition establishment in the UK seems to regard neither sucrose nor EFA as respectable areas of nutritional research. Perhaps that is the reason why the 27 lines that are devoted to EFA and prostaglandins are so poor. They are marred by misleading omissions, by an erroneous summary of the evidence relating to human requirements and the idiosyncratic phrase "membranes of structural lipids". But the committee's incorrect assertions that "all prostaglandins are metabolically derived from arachidonic acid" or that " γ -lindenic acid is the immediate precursor of arachidonic acid" make the review not only superficial but worthless.

Similar problems occur elsewhere, so that the overall impression is of a report biased in its summary of the literature. Every scientific review is, of course, similarly biased, but since this one gives no references it is impossible to tell whether the author or the reader is ignorant of the literature. Would an unbiased reader really

**Food and Nutrition Research*, (HMSO £3.80).

conclude that studies in high doses of vitamin C have resulted in "very little sound evidence" that it can have any beneficial effect and some reason to suspect it may be harmful"? Or would he remain open minded?

But the scientific review is only the sprat. The mackerel is the set of policy proposals found, in the main, as terse sentences interspersed with the reviews, and designed to give practical expression to Neuberger's three priorities.

Not one of these can be objected to; they are all worth investigation. But then, given enough time and money, so is Uri Geller. If the proposals are considered as the expression of priorities in nutrition many must be rejected. They are the thoughts of experts enthusing over past triumphs and the importance of what they wish to do next. Such enthusiasm is of importance in science, but its expression in this report is sufficiently uncontrolled that a fusillade of ideas have scattered like buckshot around the target. Although Professor Neuberger has sometimes given due priority to an outstanding research need—for example the whole subject of protein and energy metabolism—he has done a disservice by failing to regard any aspect of metabolism as less than a priority.

The committee's approach to the use of animal models also seems to lack coordination. Such models are lacking for many of the intractable problems of nutrition, and the common laboratory species are perversely disinclined to suffer from obesity, diabetes mellitus, kwashiorkor, ischaemic heart disease and many of the other great nutritional scourges. Which is probably why the diseases remain; if the guinea pig possessed L-gulonolactone oxidase, scurvy might pose quite formidable research problems. Primates are proposed at a number of points as a useful model and the limited usefulness of other animals mentioned.

In their views on primates the committee holds an Aristotelian view of animal relationships as a *scala naturae*. This is a view that has been criticised elsewhere with the admonition to choose the model for its particular functional similarity to man rather than on the basis of some vague evolutionary notion of affinity.

There is a case to be made for giving priority to comparative nutrition if we are ever to understand human nutritional disease. Interspecific generalisations like the relationship between energy expenditure and body weight can only improve our perspective on man. When the similarities are established even the species differences can be valuable. If, as the committee suggest, a considerable proportion of basal metabolic rate is accounted for by the energy cost of protein turnover,

how does the cat have a normal energy requirement but a protein requirement twice the interspecific mean?

But above all a comparative approach might teach us to look at animals, their diets and their diseases as an ecological whole. Nutritional epizootology could do much to counteract the myopia of nutritional epidemiology.

Would it work now?

Myopic, too, is the only way to describe the neglect shown by the Neuberger committee of the whole subject of social nutrition. Precious little value is placed on studies of what people eat—and virtually none on the important field of why they eat it, and why they do not. How do we persuade a person to eat what we regard as good, and avoid what we regard as harmful? No amount of heavyweight basic science in nutrition can avoid the fact that food that is not eaten has no nutritional value. Nor can any amount of enthusiasm about action at the molecular level avoid the responsibility of the nutritionists to improve human diets. That responsibility is all too often not discharged because neither nutritionists or physicians know how to alter effectively what people eat.

The omission of any discussion on social nutrition is a curiously blinkered attitude. If it was an error it will no doubt be as unfortunate as it is inexcusable. What young research worker of 'potential' will be attracted now into social nutrition? The subject, anyway, is discouraging—the experiments are often equivocal and research funds are scarce. Presumably funds will now dry up altogether.

It is a pity that Neuberger did not see fit to review the classic work of Barker, Barnicott, Burnett, Douglas,

Joy and Yudkin, or any of the other authors who seem to be aware that food is something more than the sum of its nutrients. If consulted, their views on priorities would have been something more than a lame note on how "it would be of considerable interest to review the results of advertising campaigns . . . and to assess the effect of these on the nutritional value of the diet". We do not know with any precision why or how the UK diet is changing. We do not know why nutrition education fails when advertising works.

Nutritionists are not in business to pursue uncluttered academic research but to improve the nutritional status of the population. Yet they don't know how except by draconian war-time rationing. Meanwhile the pragmatic, arcane arts of the advertising industry are being neither studied nor tested by the academic world.

In the developing world, our knowledge is even more limited. Although nutrition education has proved ineffective as a method of achieving dietary change in the UK it still flourishes as the panacea for Africa's ills. Only recently has there been any serious attempts to see if it works and why it fails. Even now the analyses are oversimplified—for example, no serious attempts are made to identify socio-economic behaviour. Africans are lumped together, or at best split into tribes and nations.

No less urgent is our need to study the sociology of nutritional science. Some field nutritionists have felt that, despite their best efforts, their role as an alien expert inevitably has an overture of racial arrogance. At its worst this is a caricature: the western bourgeois explaining to an African lady how she should prepare one of her own traditional recipes. But even at its least offensive it remains—western man and his science in judgement on another culture and its beliefs. Western man cannot even claim always to have been correct. The life and death of the protein myth, and the distorting effect it has had not only on aid but on the overall development of nutritional science, needs not merely comment but a detailed critical analysis. If we wish to change nutrition, we must understand its structure.

There are two views about the 'golden age' of nutrition. Many scientists feel that this was the vitamin era before the war, when nutrition and biochemistry were synonymous. But to the public it was of most use during the Second World War, when the state of nutrition of the nation improved. It is with use that one must be concerned, and if practical nutrition were given as high a priority as basic science, its 'golden age' could yet be to come. □

USA ratifies chemical warfare protocol

by Colin Norman, Washington

AFTER nearly fifty years of wrangling, the United States government last month belatedly ratified the most important chemical warfare treaty ever negotiated—the 1925 Geneva Protocol, which outlaws the first use in war of chemical weapons. And, for good measure, final approval was also given to a 1972 treaty which forbids the development, production and stockpiling of biological weapons.

But, encouraging as those actions are, they unfortunately do not signify that the Pentagon has lost interest in chemical weapons, nor do they indicate that the Administration is yet prepared to negotiate seriously for international chemical disarmament. Any lingering doubts on that score were dispelled late in December when it became known that even as the Senate was about to approve the Geneva Protocol, the Army was blithely pushing ahead with its plans to produce a new generation of nerve gas weapons called binaries.

For years, the Army Chemical Corps has been conducting research and development on binaries with a view to replacing its ageing stockpiles of nerve agents—estimated to amount to about 40 million pounds—with the new weapons. The idea is that since binaries consists of two relatively non-toxic components which form a lethal agent only when they are mixed together, they can be manufactured and stored much more safely than conventional nerve gases.

But last year Congress refused to grant any money for the production of binary weapons, chiefly because of arguments that if the United States were to embark on a massive new chemical weapons programme, any chances of negotiating an international chemical disarmament (as opposed to no-first-use) treaty would almost certainly have been wrecked. Such negotiations have been taking place in Geneva for the past five years under the auspices of the Conference of the Committee on Disarmament (CCD): it would clearly be difficult for the United States representatives at the talks to retain any credibility if they were placed in the position of arguing for chemical restraint while the Army is busily building up its stockpiles.

Nevertheless, in spite of production ban, the Army published a solicitation in the *Commerce Business Daily* on

December 11, inquiring whether any company would be interested in manufacturing "tor quantities" of two chemical components of binary weapons and also "artillery projectiles filled with a non-toxic chemical solution". That move clearly indicates that the Army has not dropped its plans for binary weapons and that it will almost certainly be coming back to Congress this year with another request for production funds.

Another aspect of the solicitation is also very interesting. Last year, the Army was planning to produce binary weapons with two chemicals which would form the nerve gas GB when mixed together. But the announcement on December 11 indicates that the Army is now also planning to produce a binary weapon which would form the much more persistent nerve agent VX. The gas GB quickly breaks down in the environment, but VX can remain lethal for several weeks under some conditions.

So the Army is clearly hoping to push ahead with its chemical weapons programme, but it will have a tough domestic fight on its hands. For one thing, the arguments which persuaded Congress to shut off production funds last year will be just as strong this year, added to which the new Congress is expected to be politically more liberal than the last. And for another, the

THE announcement last month that the Ford Administration has come round to the view that the Geneva Protocol includes herbicides and riot control agents places the British government in an isolated position. In February 1970 Mr Michael Stewart, then Foreign Secretary, announced in the House of Commons that the British government considers that "CS and other such gases" are outside the scope of the protocol. Although the protocol clearly says nothing about non-military use of chemical weapons, the reason for Mr Stewart's decision was believed to be the fact that CS was being used extensively in Ulster. Even at the time, such an interpretation was shared by few other countries.

● THE British Government was further embarrassed over its policy on nerve gases this week when a *Sunday Times* report revealed that the formula for the lethal VX gas had been

taken off the secret list, and was available to anyone who cared to spend an afternoon browsing in the Patent Office.

The Minister of State for Defence, Mr. Rodgers has agreed to examine the procedures followed when a chemical weapon is taken off the secret list. He gave the undertaking in a letter to Mr. Bruce Douglas-Mann, a Labour MP who tabled two questions to the Defence Secretary Mr. Mason, and expressed fears that the V-agent would be a dangerous weapon if it fell into the hands of terrorists.

Anybody can now obtain a detailed account of the process by which VX is made by applying to the Patent Office, where details were filed 14 years ago as a classified specification. Part of the patent papers were actually reproduced in the *Sunday Times* in order to indicate their availability, and the report suggested that a student, with a little ingenuity, could manage to manufacture the gas in a university labora-

tory. A photograph of the manufacturing apparatus, published after an 'open day' at the chemical warfare plant at Nancekuke, Cornwall, makes the job of the terrorist chemist that much easier.

The nerve gas codenamed VX is the most toxic of a family of V-agents produced by British chemical warfare scientists since World War Two. The gases are organic-phosphorous compounds, and were synthesised in the mid-1950s by a team at the Chemical Defence Experimental Establishment at Porton Down, Wiltshire. V-agents were not produced in bulk in the UK, but under an information-exchange agreement between Britain and America, details of the process were passed on, and formed the basis of a weapons system developed by the US Department of Defence. VX is said to be so toxic that in liquid form a drop the size of a pinhead, placed on the skin, is lethal.

Administration has been carrying out its own internal review of the binary programme. The matter is now said to be awaiting the attention of Secretary of State Henry Kissinger, and it is no secret that the Arms Control and Disarmament Agency (ACDA) has been vigorously opposing production of the weapons. It would clearly be in the Administration's political interest to abort the programme itself rather than face another hopeless battle with Congress.

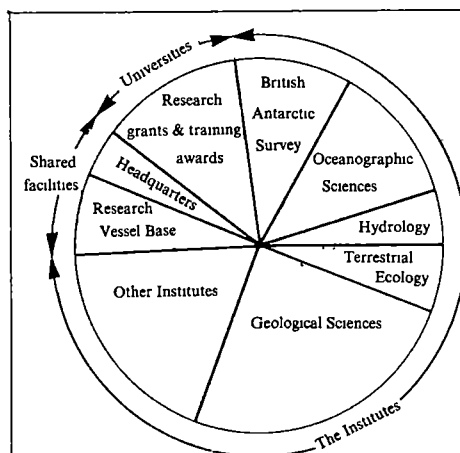

Moreover, even in military terms, the Pentagon may come to realise that the programme just is not worth the candle. It has been estimated that it will cost at least \$1,000 million to replace existing nerve gas stockpiles with binaries and since the Pentagon is always complaining about the inadequacy of the defence budget, it should be asking itself whether the money could better be applied elsewhere.

But, the ratification last month of the Geneva Protocol may at least help the CCD talks when they resume in Geneva this spring. The fact that the United States had not even ratified the 50-year-old treaty barring first use of chemical weapons was viewed by several delegations in Geneva—particularly the Soviet delegation—as evidence that the United States was not really interested in chemical disarmament, but at least that stumbling block has now been removed.

The problems with the protocol came in two parts when it was originally submitted to the Senate for ratification. (All such treaties require a two-thirds majority vote in the Senate before they become official US policy.) First, it fell foul of the chemical industry and was never brought to a vote, after languishing in the Senate Foreign Relations Committee for years, it was eventually withdrawn from the Senate. Then, in 1971, President Nixon resubmitted the treaty to the Senate for ratification.

But another impasse developed because Nixon insisted that herbicides and riot control agents are not covered by the protocol an interpretation which would have meant that, even if the United States ratified the treaty, it could continue using herbicides and tear gases in Vietnam. Senator J. W. Fulbright, Chairman of the Senate Foreign Relations Committee, did not, however, accept that interpretation. He refused to bring the measure to a vote and asked the Administration to review its position.

There the matter rested for three and a half years until Fulbright called a meeting of the Foreign Relations Committee on December 10 last year to review the situation. Faced with another embarrassing blaze of publicity the Administration finally overruled the

THE British Natural Environment Research Council (NERC) saw through half of the total Rothschild transfers in the year 1973-74 according to its recently published report (HMSO, £1.50). For that year £3.6 million worth of research was assigned to customer departments, for the most part satisfactorily—meaning that everyone carries on much as before including the NERC which goes on managing. The NERC does, however, sound a warning signal. The council doesn't reckon it has enough applied research under its wing to meet the Rothschild targets, so some "quite basic research" is being transferred to departments. The question is whether in lean times ahead basic research in a customer department's budget will present a "conflict of priorities", a delicate term for being axed.

Some of the transferred programmes do not sit too easily in customer departments. The NERC gives two examples. The geological survey of the continental shelf is a hard-to-place baby. There is £1.5 million of applied research to be transferred, but the first home for it, the Chemical and Minerals Board of the Department of Trade and Industry, turned out to be less than ideal. It looks as if it can find a foster-home with the Shipping and Marine Technology Board of the

NERC's £19 million cake divided—by means and by ends

same department but the NERC would like to see it finally adopted by the Department of Energy. On the other hand, the land Geological Survey is a much sought-after property and in order to prevent it from being torn limb from limb, the NERC has agreed to the survey being overseen by a consortium comprising, *inter alia*, the NERC's chairman, Sir Peter Kent, and representatives of the departments of Trade, Industry, Environment, Scottish Development and of the Welsh office.

The Institute of Geological Sciences is reported to be finding difficulty in recruiting and keeping staff to work on the independent analysis of North Sea commercial data that it attempts to carry out. Uncompetitive salaries in the scientific civil service are blamed.

Further, significantly fewer people applied for research studentships this year, the report notes, but those that did were distinctly more willing to move to a different university for their second degree.

As the figure shows, universities continue to comprise only a modest fraction of the NERC's commitment. Britain's terrestrial toe-hold in the Antarctic, gets almost as much as the total expenditure in universities.

Pentagon, and Dr Fred Iklé, Director of ACDA, announced that President Ford now accepts that the protocol bars first use in war of all chemical weapons, including herbicides and tear gases. The measure then sailed through the Senate without opposition.

The actual effect of all this on progress in the CCD talks is uncertain at present, largely because of the looming threat of the binary programme. But, assuming that talk of producing binaries dies away this year, the chief stumbling block in Geneva will become the difficulty of making sure that a chemical disarmament treaty can not

be violated. One possibility, however, is that a treaty banning further production of lethal chemical weapons will first be negotiated. That would prevent chemical proliferation—and also reduce the capability of both the United States and the Soviet Union, since existing nerve gas stocks will slowly deteriorate. A ban on stockpiling would then be negotiated later. A Japanese proposal along those lines is now receiving close attention in the United States.

The key to the whole business, however, is what happens to the binary programme. □

WHILE international attention has been focused on plans for nuclear power stations in Israel (and neighbouring countries), Israeli scientists have continued their search for new sources of energy, or for more efficient means of exploiting old sources. Everything is being considered, from the proposal of a scientist at the Haifa Technion to construct 10,000 giant energy-generating windmills to the scheme of his colleague for a thermonuclear power reactor.

Research continues on an obvious energy source in this sub-tropical climate—the Sun. Unfortunately, solar energy has not proved itself economically viable except for the heating of household water supplies. And its benefits in this sphere are cancelled out, in the eyes of environmentalists, by the ugliness of the roof-top solar energy installations which, together with the omnipresent television aerials, manage to create a particularly horrifying urban skyline.

Even though Israel has far more ample supplies of solar radiation than of water, there is even talk of constructing a 120-MW hydroelectric station near the northern end of the Sea of Galilee.

A small hydroelectric station was actually opened on the River Jordan, south of the Sea of Galilee, way back in 1932, but it has been out of action since the 1948 war. The proposed new plant would be placed at a point where

the Jordan plunges 830 feet down into the northern end of the Sea of Galilee.

Utilisation of oil shale is also under active consideration thanks to Professor Yehoshua Schachter of Bar-Ilan University, an Orthodox Jewish institution where all the scientists wear skullcaps. Professor Schachter believes that the estimated 700 million tons of oil shale recently discovered in the Negev Desert would be sufficient to generate some

Letter from Israel

from Nechemia Meyers, Tel Aviv

1,000 MW of electricity for 30 years. This is an impressive figure in Israeli terms, as the country's present generating capacity is 1,600 MW.

Schachter's plan, now being studied by a government-appointed engineering company, calls for the shale to be burnt on-site to generate electricity, rather than for the oil to be extracted first and then burnt at a power station. Such a direct burning process has been used successfully in West Germany and Estonia, and skyrocketing fuel prices have made it look attractive here.

Professor Schachter also emphasises the fact that the power-generating facility he suggests would be particularly valuable in wartime, when other fuel imports might be cut off.

• War, of course, could come here at almost any moment, and in the mean-

time Israel has a full-scale anti-terror campaign of her hands, one in which scientists have already played some role. Their contributions, unfortunately, have not always been utilised. For example, a reliable Israeli-developed device for 'sniffing' explosives was not used to check the explosives-laden suitcase of a young man who arrived recently at Lydda (Ben-Gurion) Airport. The next day he used the explosives to make bombs which he subsequently exploded inside a Tel Aviv cinema.

• Israel's special problems made it the natural venue for an International Conference on Psychological Stress and Adjustment in Time of War and Peace, which opened at the University of Tel Aviv on January 6. One of the papers presented at the conference described a study carried out by Dr Avner Ziv, University of Tel Aviv, on 'shelter children', youngsters in border areas who must spend extended periods in underground shelters because of recurrent shellings. Dr Ziv and his colleagues found that kibbutz children under bombardment adjusted to the stresses of the situation much more successfully than did children at nearby small towns. He speculates that the highly organised social structure of a kibbutz, and the fact that it operates almost like an extended family, may provide a more secure atmosphere for children in times of crisis than does the nuclear family in a town.

AFTER a year and a half of actively, but silently consulting everybody, the Dutch Science Minister Mr F. H. P. Trip, finally ventured into the limelight to present his 'Purple Book' on science policy.

Mr Trip is a most remarkable man. He has roots in industry (as a managing director of Naarden Chemie, a specialised company with more people in its laboratories than in its production departments) and in academe (as President-elect of Utrecht State University), so many regarded him as the ideal science manager. Also, surprisingly, he is a member of one of the most radical political parties in the Netherlands.

Yet, according to his new plans, he is not after radical changes in the structure of science policy. The universities maintain their rate of income per student and their freedom to handle the sum of Dfl 1,000 million as they please. But they are requested, if not required, to set up a reasonable book-keeping system for their research projects, in accordance with the government's technical guidelines. In view of the present state of the average university administration, implementation of this rule will call for a major effort.

Mr Trip's purple book

from Arie de Kool, Rotterdam

Something like Dfl 100 million a year is now handed out by the ZWO, the organisation for pure scientific research. It is rightly being claimed that this rather insignificant amount has a very considerable steering effect. The Foundation for Basic Medical Research funded by the ZWO, claims to coordinate about Dfl 80 million worth of research on a budget of Dfl 4 million. They get there by adding a man here and a centrifuge there—on conditions, of course. The ZWO (and the Royal Academy, as far as its own institutes are concerned) will be transformed into a Council for Scientific Research (RWO), with departments for fields like physics, life sciences and social sciences. Each department could have many 'working groups', consisting basically of everybody working in a specific discipline. There could be working groups for solid state physics, molecular biology, sociology of the family and so on.

The working groups elect ten mem-

bers of the department, five others are appointed by the Academic Council (the cooperative institution of the universities), and five more, together with a president, by the government.

Some Dfl 1,000 million is spent on more or less applied research sponsored by the government. This will stay under direct ministerial control although the ministers concerned will receive advice, and even planning schemes to cover several years from sectorial councils, such as a council for environmental problems, one for maritime research or the environmental movement.

The councils are to be meeting points for government and producers and consumers of science. So each council consists of some government representatives, some scientists from the institutes concerned and some people from 'society'—industrialists, labour union representatives and people from the environmental movement.

Mr Trip also hopes that industry (in the Netherlands some 75% of industrial research and development is done by five multinational companies) will be open about its own projects, so that good coordination of government-funded research and development will be possible. □

correspondence

UNESCO

SIR,—As visiting scientists at the Weizmann Institute, we find the recent UNESCO anti-Israel resolution doubly abhorrent

First, as scientists and educators, we are appalled at the biased, politicised and cowardly vote, which has made a travesty of an organisation established to help wipe out just such ignorance and prejudice

Second, being in Israel we have had the opportunity to explore Jerusalem—the old, the new, the restored, the excavated—and thus to recognise the absurdity of the claim that the excavations carried out in the Holy City have changed its character

We call on our fellow scientists to join us in protesting UNESCO's moral bankruptcy and in demanding that the organisation abandon politics and return to dealing with science, education and culture

Yours faithfully,

L ANDERSON (University of Illinois), E E A BROMBERG (University of Wisconsin), C BRUNK (University of California), D CAHEN (Northwestern University), A COGOLI (ETH, Zurich), S COHEN (State University College at Buffalo), R COOPER (University of Pennsylvania), B S DUDOCK (State University of New York at Stony Brook), S EDELSTEIN (Cornell University), D FAIMAN (CERN), A FRIMER (Harvard University), R A GELMAN (Case Western Reserve University), A KRSTOSEK (University of Oregon), S J LEBOVICH (University of Washington), J MANZ (Technische Universität, Munich), S B MIZEL (Colorado State University), J PRIVES (Columbia University), H SCHMITT (Free University of Brussels), J SCHULTZ (University of California), P B SIGLER (University of Chicago), A SOUDAK (University of British Columbia), M THALER (University of California), S WEISROSE (University of London), H YAMASAKI (Hiroshima University), M ZEICHER (Vrije Universiteit, Belgium)

Another African Chalicothere

SIR,—Among a large collection of vertebrate fossils from the Lukeino Formation which I made recently I found the proximal phalanx of a large Chalicothere. Its size suggests that it belongs to *Ancylotherium hennigi* Dietrich, although if so that species will prove to be the oldest known specimen (~6.5 Myr)

Chalicotheres are now known from several deposits in Africa—the Lower Miocene of Rusinga and Songhor, Kenya, the Pliocene of Kaiso, Uganda, from which the first African Chalicothere was recognised (C W Andrews, *Nature*, 112, 696, 1923), and Lower Pleistocene deposits such as Olduvai, Tanzania (P M Butler, *Bull Br Mus Nat Hist Geol*, 10, 165–237, 1965). In the Baringo area Kenya, they have been recognised from the Chemeron Formation (~4 Myr) and now from the Lukeino Formation

On discovery of the Lukeino fossil, I described a Chalicothere to my field assistant, Mr Kiptalam Chepboi, who assured me that I had accurately described a *Chemosit*. I repeated the description to several other local people, all of whom gave the same opinion. The *Chemosit* is an animal of Kalenjin myth, on which the 'Nandi Bear' is supposed to have been based (*Nature*, 112, 696, 1923 and B Heuvelmans, *On the Track of Unknown Animals*, Rupert Hart-Davis, London, 1958) and it was the first discovery of a Chalicothere in Africa that prompted Andrews to enquire whether the Chalicothere was still extant and whether it formed the basis of the myth. It is therefore of great interest to obtain further information from an independent source, separated by more than two generations and hundreds of miles, that indeed the *Chemosit* and the Chalicothere closely resemble one another

It is unlikely that the Chalicothere is still extant, even in the depths of the Zaire forests, but it is not inconceivable that it survived until the recent past, entering local mythology before finally dying out

MARTIN PICKFORD
Queen Mary College, London

Asbestosis

SIR,—W P Howard's comment (December 13) on Peter J Smith's article (October 18), "For those in peril on the factory floor" which dealt with the industrial hazards of asbestos, itself deserves comment. It is true that conditions in the industry are incomparably better than they were in some factories 40 years ago but the occurrence of an average of 139 new cases of asbestosis a year in Britain still emphasises a formidable hazard. Mr Howard, writing from a London office where he only inhales the few asbestos fibres normally present in an urban atmosphere, may have every confidence that in coming years the number of cases will be reduced to a very low level indeed, but this confidence suggests a complacency that is not, I am sure, characteristic of the industry as a whole. We do not know to what level the concentration of asbestos in the atmosphere must be reduced before the hazard will disappear. The Maximum Admissible Concentration level is a guess

That asbestos is a dangerous commodity cannot be too strongly emphasised and, although it is indispensable for certain purposes, it should be used with discretion. Because of television programmes describing the occurrence of asbestosis and cancer in workers in Hebden Bridge, the public has become aware of dangers that can arise when the material is handled indiscriminately. A general review (*The Biological Effects of Asbestos*, distributed by the World Health Organisation) that summarises the report of a working conference on the biological effects of asbestos, sponsored by the International Agency for Research on Cancer, indicates that all the major commercial types of asbestos can cause cancer and that there is strong evidence to relate past exposure to asbestos with mesotheliomas, a distressing cancer of the pleura that covers the lung

The danger may not relate only to employees. One paper in the same report represents a study of the incidence of mesotheliomas in the city of Hamburg-Bergedorf in the years 1958–68. In the city as a whole the incidence was 0.056%, in the residential area around one factory it was 0.96%. Cases considered to be occupational were excluded

P F HOLT
University of Reading

Research in India

It is only natural that Dr Macdonald (*Nature*, November 15, 1974)—with his World Health Organisation (WHO) and Genetic Control of Mosquito Unit (GCMU) connections—should have reacted the way he has, to a part of my item on work on the genetic control of mosquitoes (*Nature*, September 20, 1974) I am afraid I cannot agree that there was anything “misleading”, “misinformed” or “erroneous” in statements which pointed out disparities between population needs and the GCMU’s priorities in choosing its programmes. The military implications too cannot be summarily dismissed, as Dr Macdonald has done, by merely hiding behind the familiar generalisation that all research results, in theory, could be misused. The fact of the matter is that there have been instances of misapplications. It may well be recalled that the defoliants employed by the US Army in Vietnam were reported to have been first tested for their effects in some Latin American countries. I cannot say what were the specific long-term benefits from these tests to the Latin American Communities.

Then there is the case of childhood malnutrition. For years now, we have been led to believe (by all kinds of agencies including UN and others) that protein deficiency in the Indian diet is the major cause of malnutrition in India. Consequently, vast amounts of Indian (as well as foreign) money were diverted towards high-protein food programmes, whereas the problem all along—we are now told—has been one of simply not enough food.

Moreover, studies “specifically designed for the long-term benefit of the community” should surely be able to stand a little scrutiny, and a probe into the whole affair can only result in clearing the air and, I hope, lend support to contentions like Dr Macdonald’s, and I and many others in the scientific community shall be happier for it. Little inconveniences like these, I am afraid, will remain a foreign scientist’s lot (not only in India but elsewhere) so long as instances of the academic and scientific communities providing cover for nefarious activities by their governments continue to surface.

Yours faithfully,
NARENDER K. SEHGAL

Jullundur

SIR,—The belated comments on United States Defense Department and National Museum activities in India by N K Sehgal and A N D Nanavati (*Nature*, September 20, November 29) need to be considered in relation to

some other past history.

So far as I can make out the most revealing information is provided by William E Small in *Scientific Research* (3, (25), 27, December 9, 1968), where investigations of bird diseases transmissible to man in Brazil and the biology of the north central Pacific by the Smithsonian Institution (the US National Museum) were identified as supported by the US Defense Department chemical and biological (CB) warfare research centre at Fort Detrick in Maryland. The resulting furore reached a climax the following February, as reported in the *Washington Post* and *New York Times* on February 5 and the London *Times* and *Guardian* next day, where it is alleged that Baker Island in the central Pacific had been chosen for tests. Eventually President Nixon announced on November 25, 1969 that the USA would abandon CB warfare except for a small defensive programme, though the *Times* reported on September 21, 1971 that stocks of tularaemia, anthrax, Q fever and Venezuela equine encephalitis organisms were retained and work continued at Dugway, Utah, the place where 6,000 sheep were inadvertently killed in a mismanaged nerve gas experiment in March 1968.

Although this activity may suggest that the US Defense Department, in collaboration with the Smithsonian Institution, also financed a Migratory Animal Pathological Survey from Korea through the Far East and India to the eastern Mediterranean at much the same time, as far as one can make out the actual work was normally delegated to irreproachably upright citizens who succeeded in making very good use of the funds provided, to such an extent that the people most likely to take offence, the Russians (who were incidentally carrying out similar activities of their own), were happy to co-operate, as reported by Mr Nanavati, though the Chinese refused to do so. In consequence the withdrawal of US funds following criticism of the Defense Department has resulted in a sad gap in ornithological work in the Far East especially, where one could wish for a less controversial alternative source of money. Mr Sehgal may rest assured that whatever the original object of the Migratory Animal Pathological Survey, a lot of people have scrutinised its activities rather carefully and found nothing to complain about except some roughness in handling captive birds, so that many of us who were once among the foremost critics of its possible original object would now like to see some means found to keep it in being.

As many people have already remarked, it also seems a pity that the

Smithsonian Institution ever allowed its activities to become so closely associated with those of the US Department of Defense, and it hardly seems surprising that people in India remain suspicious.

Yours faithfully,

W R P BOURNE

University of Aberdeen

Ghost families

SIR,—There are even families of ghost writers (December 6) *Proc 5th int Conf Soil Mech* (1961) lists in its Author Index not only F Asce (II, 105) but also his more prolific younger brother M Asce (I, 517 and II, 117). Is there a case for forming a Society of Irreproducible Scientific Authors?

Yours faithfully,

PHILIP I LEWIN

Building Research Station,
Garston, Watford, UK

SIR,—May I add to the Christmas season of ‘ghost authors’ with my own favourite. A paper on a mermaid foetus is quoted in the Cumulative Index Medicus, and also by at least one subsequent author, as Williams, H I, and Lumpur, K, (1962) *Arch Path (Chicago)*, 74, 472. In fact reference to the paper itself shows that Dr Williams, the sole author, wrote his report from Kuala Lumpur.

Yours faithfully,

MARTIN D’A CRAWFURD

The University,
Leeds, UK

A hundred years ago

THE great solar eclipse of 1868 was visible in Siam, as the 1875 eclipse will be. The then reigning Siamese king had not invited any European astronomer, but the French Government sent an expedition, who located themselves in Malacca for the purpose of taking spectroscopic observations. The King of Siam, who professed to be an astronomer, came with a royal train and a large army to observe the sun and perhaps the sun-observers. The observations were very successful indeed, but the French astronomers had located themselves on marshy land and were almost all attacked by fever, of which they were cured only on their return to France. Such was not the case, however, with their royal guest, who was also attacked, and died a few months afterwards from *Nature*, 11, 216, January 14, 1875.

Understanding the control of vitamin D synthesis or taking a short cut through South America

from a Correspondent

CHOLECALCIFEROL is classified as a vitamin only because its synthesis from 7-dehydrocholesterol is effected by ultraviolet light rather than by an enzyme. Consequently if there is limited exposure to sunlight, the diet must be supplemented with cholecalciferol. 1,25-dihydroxycholecalciferol ($1,25-(OH)_2D_3$), the active form of cholecalciferol, is more properly defined as a hormone since it is synthesised solely in the kidney¹ from its immediate precursor 25-hydroxycholecalciferol ($25-(OH)D_3$). This metabolite is involved in translocation of calcium across cell membranes and in calcium homeostasis, and has potential uses in the treatment of metabolic bone disease. There is therefore much interest in the control of $1,25-(OH)_2D_3$ production and, since the chemical synthesis of $1,25-(OH)_2D_3$ cannot be carried out in high yield, in natural sources of the hormone.

The control of $1,25-(OH)_2D_3$ production has now become a source of controversy with two possible mechanisms being proposed, a recent paper² has indicated the complexity of the relationship of $1,25-(OH)_2D_3$ with parathyroid hormone. Most groups believe that $1,25-(OH)_2D_3$ production is primarily under the control of parathyroid hormone. This is supported by the changes which occur in chick mitochondrial $25-(OH)D_3$ -1-hydroxylase activity in response to changes in parathyroid hormone concentrations³. Also within hours of thyroparathyroidectomy the concentrations of $1,25-(OH)_2D_3$ fall in blood and intestinal mucosa of rats on a low calcium diet, but injection of parathyroid hormone restores $1,25-(OH)_2D_3$ concentrations to normal⁴. The rate of conversion of $25-(OH)D_3$ to $1,25-(OH)_2D_3$ in an isolated renal tubule preparation can be increased by the addition of parathyroid hormone or cyclic AMP to the incubation media⁵. Both the concentrations of $1,25-(OH)_2D_3$ in tissues of rats and chicks and the activity of the $25-(OH)D_3$ -1-hydroxylase enzyme measured *in vitro* are responsive to changes in levels of calcium in the plasma⁴ and media³ respectively. But these groups felt that calcium does not

control $1,25-(OH)_2D_3$ production first, because the enzyme activity measured *in vitro* was not related to the plasma calcium concentrations in the bird from which the kidneys were obtained³, second, the transfer of rats from a low calcium to a high calcium diet results in a rapid decline in plasma calcium concentrations whereas the $25-(OH)D_3$ -1-hydroxylase activity remains elevated for very much longer⁶. Calcium affects the activity of the $25-(OH)D_3$ -1-hydroxylase enzyme by preventing electrons from flowing into the 1-hydroxylase system from a specific NADPH generating system. Under these conditions added NADPH provides the necessary reducing equivalents⁷.

The alternative mechanism for control of $1,25-(OH)_2D_3$ production has been proposed by Professor MacIntyre and his group⁸. They have not seen an increased production *in vivo* of $1,25-(OH)_2D_3$ in response to parathyroid hormone⁹ nor in their isolated renal tubule preparation could parathyroid hormone raise $1,25-(OH)_2D_3$ production though dibutyl cyclic AMP did have a positive effect¹⁰. If calcium was omitted from the incubation medium however, parathyroid hormone did stimulate $1,25-(OH)_2D_3$ production. Since they found added parathyroid hormone to be increasing cyclic AMP concentrations in their isolated renal tubules they have postulated that the influx of calcium into kidney cells, known to occur in response to parathyroid hormone, has negated the effect of the increased cyclic AMP concentrations. They have now incorporated their findings in a hypothesis which proposes that $1,25-(OH)_2D_3$ production is subject to feedback control.

The key observation was the decreased capacity of renal tubules to synthesise $1,25-(OH)_2D_3$ if the tubules had first been pre-incubated for 150 min with the hormone. This inhibitory effect of the $1,25-(OH)_2D_3$ was not due to competition by the hormone for the active sites on the $25-(OH)D_3$ -1-hydroxylase enzyme and was not detected if the renal tubules were incubated with the hormone in the presence of

actinomycin D. The authors propose that $1,25-(OH)_2D_3$ stimulates by a nuclear action the synthesis of a protein, possibly calcium-binding protein, which is involved in the mechanism of calcium uptake by kidney cells. In the presence of this protein, tubular calcium is reabsorbed and the consequent raising of kidney cell calcium concentration inhibits $1,25-(OH)_2D_3$ production. There is therefore a cycle of events in which $1,25-(OH)_2D_3$ production is controlled by its own action on the tubular reabsorption of calcium.

Crucial to the validity of this hypothesis are the limits to any variation in the concentration of cellular calcium. This information is unfortunately difficult to obtain with confidence because under certain conditions mitochondria take up extremely large amounts of calcium. Even so the changes in $25-(OH)D_3$ -1-hydroxylase activity which have been observed in response to changes in calcium concentration are inadequate to explain the changes in $1,25-(OH)_2D_3$ production *in vivo* unless the cell calcium concentration varies over enormous ranges. Thus a 7.5 fold change in calcium concentration gives rise to only a 50% inhibition in $1,25-(OH)_2D_3$ production *in vitro*, whereas several-fold variations in $1,25-(OH)_2D_3$ production rates can be observed *in vivo*³.

These variations might, however, have other causes. For example, any measures that lower serum inorganic phosphorous and hence kidney phosphorous concentrations increase $1,25-(OH)_2D_3$ production⁴. In addition there may be multiple effects of parathyroid hormone on $1,25-(OH)_2D_3$ synthesis. Favus, Walling and Kimberg² have found that the response of rats to parathyroidectomy varies with time. They found that there is a diminished intestinal calcium transport 72 h after surgery, but parathyroidectomised rats adapted to a low calcium intake over 21 d. This adaptation to a low calcium diet is known to be $1,25-(OH)_2D_3$ dependent. In interpreting these and other results it should, however, be appreciated that an absolute dependence of $1,25-(OH)_2D_3$ production on

the presence of parathyroid hormone has never been shown. In parathyroidectomised animals some 25-(OH)₂D₃-1-hydroxylase activity always remains. In accord with this Favus *et al* found plasma concentrations of the hormone were low but levels in the intestine were normal 21 days after parathyroidectomy.

Recently the South American plant *Solanum malacoxylon* has been seen as a possible source of 1,25-(OH)₂D₃. Cattle and other animals eating this shrub show features similar to those of hypervitaminosis D including hypercalcaemia, hyperphosphataemia, vascular and ectopic calcification, wasting and eventual death. The derangement of calcium metabolism probably derives mainly from the increased intestinal absorption of calcium. There is some evidence that the active principle in *S. malacoxylon* is 1,25-(OH)₂D₃ rather than the other vitamin D metabolites¹¹.

S. malacoxylon given orally to chicks induces synthesis of calcium-binding protein (CaBP)^{11,12}. This protein seems to be involved in calcium absorption and its synthesis is dependent upon 1,25-(OH)₂D₃. The action of the leaf is not inhibited by the inclusion of strontium in the diet, a metal which inhibits the conversion of 25-(OH)D₃ to 1,25-(OH)₂D₃ by the kidney enzyme system, suggesting that the active principle is not metabolised by the kidney 25-(OH)D₃-1-hydroxylase prior to its action in the intestine. Corradino and Wasserman¹³ have shown that the aqueous extract of the leaf has two other actions similar to that of

1,25-(OH)₂D₃. Thus it is active in stimulating within 12 h CaBP synthesis and calcium absorption in organ cultured chick duodenum, again implying that if any metabolism of the active principle is involved it can occur in the intestine. As in the case of 1,25-(OH)₂D₃, the induction of CaBP in this system is inhibited by actinomycin D. In addition 1,25-(OH)₂D₃ and the aqueous extract of the plant induce *de novo* CaBP synthesis in 18-day-old chick embryo duodenum, whereas 25-(OH)D₃ is much less potent in the embryo in this regard and vitamin D seems to be without activity.

Little information is available on the chemical nature of the active principle. If it is 1,25-(OH)₂D₃ then its water solubility implies that it is attached to large polar moieties and the hydrolysis of this complex may account for its delayed action^{12,13}. Its identification is awaited with interest.

dence), has meant that these drugs can be used as pharmacological tools to study the function of endogenous prostaglandin release in the body (see Ferreira and Vane, *The Prostaglandins*, volume 2, edit by Ramwell, Plenum Press, New York, 1974 for review).

An alternative way of studying physiological events in the absence of prostaglandins is to actively immunise animals against them, prostaglandins can easily be made immunogenic by coupling them to a carrier protein such as bovine serum albumin. Active immunisation against prostaglandins has recently been shown to afford a certain protection against inflammatory stimuli (Ferreira *et al*, *Prostaglandins*, in the press). Using similar techniques Horton and Poyser have obtained further evidence that prostaglandin F_{2α} is involved in luteolysis in the guinea pig (*Prostaglandins*, **5**, 349, 1974). This experiment adds further support to the idea (now widely accepted) that prostaglandins are involved in luteal regression in several animal species (Pharris, *Peispec. Biol. Med.*, **13**, 434, 1970) though apparently not in man. Other aspects of the reproductive process are also susceptible to modification by prostaglandins (see Persaud, *The Prostaglandins*, volume 2, edit by Ramwell, Plenum Press, New York, 1974). Prostaglandins are in clinical use for the termination of pregnancy and induction of labour and an interesting corollary to their stimulating action on the myometrium is the manner in which aspirin-like drugs delay parturition in both man and animals (see Persaud, cited above). These effects reinforce the view that endogenous PG production in the uterus is the final pathway for expulsion of the contents.

When Vane made his observation that aspirin inhibited prostaglandin biosynthesis in a cell-free system (*Nature*, **231**, 232, 1971) there was already some evidence indicating that prostaglandins were involved in the pathogenesis of inflammation and fever. Thus, as Vane pointed out, inhibition of prostaglandin biosynthesis could explain the well known anti-inflammatory and antipyretic effects of aspirin. Since then a link has been established between inhibition of prostaglandin biosynthesis and the analgesic actions of aspirin-like drugs (Ferreira, *Nature new Biol.*, **240**, 200, 1972; Ferreira, Moncada and Vane, *Br. J. Pharmac.*, **49**, 86, 1973). Important features of the aspirin-like drugs are that the analgesia they produce is mild and that they act peripherally (Lim, *Arch. int. Pharmacodyn.*, **152**, 25, 1964). By contrast the narcotic analgesics are extremely potent drugs which act within the central nervous system and do not have any direct effect on prostaglandin biosynthesis. Recently,

Aspirin, prostaglandins, endoperoxides and platelets

from R. J. Flower

DURING the first six months of 1974 almost 500 publications on prostaglandins were cited by *Index Medicus*, this compares with some 400 publications *per annum* two years ago, approximately 170 in 1970, fewer than 100 in 1968, and only 25 in 1966. It is not difficult to understand this tremendous interest in prostaglandins: almost all mammalian cells possess the enzymatic machinery (generally known as 'prostaglandin synthetase') for the synthesis of prostaglandins from precursor fatty acids; furthermore, biosynthesis and release of prostaglandins from cells can be evoked by a wide range of physiological, pharmacological or pathological stimuli, and the different prostaglandins which are produced have a wide spectrum of pharmaco-

logical activity in concentrations often as low as 10⁻⁸M. These properties make prostaglandins obvious candidates for mediators of a wide range of physiological events.

Physiological functions

Enormous impetus has been given to research on their physiological function by the discovery that the 'aspirin-like' drugs inhibit prostaglandin biosynthesis (Vane, Ferreira, Moncada and Vane, Smith and Willis, *Nature*, **231**, 1971). These observations have since received widespread confirmation. The blockade of prostaglandin synthesis by drugs of the aspirin type, being unique, specific, and common to almost all tissues and all species so far examined (see Flower, *Pharmac. Rev.*, **26**, 33, 1974 for evi-

Fig 1 Proposed reactions for generation of cyclic endoperoxides and prostaglandins from arachidonic acid This scheme is based largely on the work of Nugteren *et al*, *Rec Trav Chim Pays-Bas*, **85**, 405, 1966, Nugteren and Hazelhof, *Biochim Biophys Acta*, **326**, 448, 1973, Hamberg and Samuelsson, *J biol Chem*, **242**, 5336, 1972, *Proc natn Acad Sci U S A*, **70**, 899, 1973 and Hamberg *et al*, *Proc natn Acad Sci U S A*, **71**, 345, 1974 Only the ring structures of the prostaglandins have been drawn, X and X¹ refer to the appropriate hydrocarbon chains I=isomerisation, R=reduction, ?=enzymic or non-enzymic MDA=malondaldehyde Although this scheme shows the conversion of arachidonic acid into G₂, H₂, E₂, and so on, the conversion of di-homo- γ -linolenic acid probably proceeds by an analogous pathway

however, an interesting and provocative hypothesis by Collier's group (see *Nature*, **248**, 241, 1974, and **252**, 56, 1974) suggests that these narcotic drugs may exert their effects by preventing the stimulation of brain adenylyl cyclase by E-type prostaglandins

Endoperoxides—the 'intermediates'

One of the most significant advances of the last two years has been the isolation and characterisation of two intermediates in the conversion of precursor fatty acids to prostaglandins. These intermediates are of interest to the biochemist because prostaglandin synthesis is an unusual type of oxygenation reaction. They also interest the pharmacologist, for Gryglewski and Vane (*Br J Pharmac*, **45**, 37, 1972) have suggested that 'rabbit aorta contracting substance' (RCS—a potent smooth muscle contracting factor first reported by Piper and Vane in 1969 whose release from perfused guinea-pig lungs during anaphylaxis is blocked by aspirin) was an intermediate in prostaglandin biosynthesis. Hence many workers had been anxious to test the biological activity of the intermediates.

The precursors of prostaglandins are the 20-C essential fatty acids. There are several groups of prostaglandins distinguished by the nature and geometry of substituent groups in the ring (for example E, F, D) and the number of double bonds in the side chains (for example E₁, E₂, E₃, F₁, F₂, F₃) all of these can be produced by the synthetase complex from the appropriate precursor. In 1965 Samuelsson proposed the existence of a common intermediate—a "cyclic endoperoxide"—which once formed could break down to either E, F, or D type prostaglandins. Two such endoperoxides have now been isolated by Samuelsson's group (*Proc natn Acad Sci U S A*, **70**, 899, 1973, *ibid*, **71**, 345, 1974) and by Nugteren and Hazelhof (*Biochem Biophys Acta*, **326**, 448, 1973). The first 'stable' product to be formed by the oxygenation reaction is called by Samuelsson's group 'prostaglandin (PG) G' and by Nugteren and Hazelhof '15-hydroperoxy PGR', the second intermediate has been named 'PGH' by Samuelsson and 'PGR' by Nugteren and Hazelhof (see Fig. 1). Both the endoperoxide intermediates are very unstable in aqueous solution,

spontaneously decomposing to prostaglandins (half-life approximately 5 min). They can, however, be isolated in some organic solvents and are stable in dry acetone at -20°C for some months.

Their instability in aqueous media has led to difficulties in the testing of the biological activity of these 'prostaglandins'. Generally the endoperoxides have greater smooth muscle contracting activity than the prostaglandins. On the isolated rabbit aortic strip the endoperoxide had a biological activity of 1-2 orders of magnitude greater than those of prostaglandins themselves and initially it seemed as though the activity of the endoperoxides could account for the RCS of Piper and Vane. But a careful comparison of the properties, especially of the breakdown rates of the endoperoxides and of RCS, has made this identity less likely. Thus in addition to the endoperoxides there may be at least one more biologically active intermediate in prostaglandin biosynthesis.

Endoperoxides also seem to have a potent biological action as platelet aggregating agents. In 1973 Willis and Kuhn (*Prostaglandins*, **4**, 127, 1973) reported that preparations of prostaglandin synthetase generated a "labile aggregation-stimulating substance" (LASS). This substance was rapidly generated enzymatically from arachidonic acid (but not from other related fatty acids) and its formation was blocked by aspirin. Early in 1974, a further paper by Willis (*Prostaglandins*, **5**, 1, 1974) described the properties of LASS, observing that it "cannot be distinguished" from the endoperoxides. Almost simultaneously a report by the Swedish group appeared (Hamberg *et al*, *Proc natn Acad Sci USA*, **71**, 345, 1974) in which they reported that purified preparations of PGG₂ or PGH₂ were extremely potent platelet aggregating agents in concentrations of 10–300 ng ml⁻¹, furthermore during aggregation of platelets with thrombin, endoperoxide was released in similar concentrations into the medium. Later in 1974 a similar report appeared (Smith *et al*, *J clin Invest*, **53**, 1468, 1974) confirming and extending these findings. Interestingly, only the endoperoxides from arachidonic acid (that is, the precursors of G₂, E₂, F₂, D₂ and so on) aggregate platelets, the endoperoxides formed from di-homo-γ-linolenic acid (the precursor of G₁, H₁, E₁, F₁, D₁ and so on) do not.

These data help to explain why inhibitors of prostaglandin biosynthesis such as aspirin block platelet aggregation, whereas PGE_2 has only a very weak aggregating action and PGE_1 actually inhibits aggregation. It seems that in platelets the final products of prostaglandin synthetase are relatively inactive end products of the synthetic

reaction and one wonders whether a similar situation obtains in some other systems. Since prostaglandin synthesis (hence endoperoxide generation) can be initiated by damage to cells and tissues, workers from each group have pointed out that endoperoxides are most likely the trigger for platelet thrombus formation at wound sites.

Doses of aspirin which block PG synthetase are (generally speaking) well tolerated, implying that prostaglandin synthetase is not an enzyme vital to the existence of the organism. This accords with the view that prostaglandins are modulators of physiological processes, perhaps mainly involved in local communication between cells, especially in defensive reactions induced by damage or stress. But, because of the exponential increase in prostaglandin literature, a few more years will have to elapse before prostaglandins are assigned a definite role among the body's homeostatic mechanisms.

Ecologists classifying plants

from Peter D Moore

It is said that when a soldier is confronted by a static object he will be inclined to paint it, a biologist placed in the same situation will attempt to classify it. By the beginning of this century, when the vast bulk of larger animals and plants had been placed into seemingly appropriate taxonomic pigeonholes, a rising breed of biologists, now classified as ecologists, began the formidable task of sorting entire communities of species into meaningful groups. Starting with the belts of climatically determined vegetation on a global scale, they worked their way down to the level of habitats. In Britain this descriptive age culminated in the production of Tansley's *The British Islands and their Vegetation* (Cambridge, 1939), in which vegetation types were defined on simple criteria, mainly the dominant species. On the Continent a more elaborate system was developed by Braun-Blanquet in which vegetation types were characterised by plant species which were confined to any given association (so-called 'faithfuls'), these were considered to be of narrower ecological amplitude and therefore more specific indicators of the environment than were the dominants used in the British system. In a modified form, this system remains the standard approach to vegetation description and classification throughout the European mainland.

In Britain the Braun-Blanquet system has never really established itself, partly because of the general poverty

Another rock term bites the dust

from L. F. Penny

At last the enigma of the Hesse Till is solved. This, the topmost member of the Devensian (last glaciation) boulder clays on the east coast of England, which most geologists have hitherto regarded as a till sheet in its own right, is now shown by Dr Madgett to be nothing more than the soil profile at the summit of the succession (this issue of *Nature*, page 105).

To be sure, this solution has occasionally been suggested before. Eighty years ago Carvill Lewis suspected it (*Glacial Geology of Great Britain and Ireland*, 209, 1894). Bisat was getting warm in 1940 when he found that the Hesse Till inland (Madgett's Zone C) was different from that on the coast (Zone A), but he was not thinking of a pedological explanation (*Proc Yorks geol Soc*, 24, 148, 1940), and more recently the same doubt has been expressed by Fenton (*E Yorks Field Studies*, 2, 3, 1969). But suspicion is one thing, and proof is another, it is this that is now presented, as a result of the application of modern pedological methods to what was previously regarded as a purely geological problem. Briefly, the so-called Hesse Till in Yorkshire lies sometimes on the Drab Till and sometimes on the Purple Till, and it is now identified, where it overlies the Drab, as weathered Drab, and where it overlies the Purple Till, as weathered Purple. And this is why Bisat's "inland Hesse" (which lies on Drab or directly on Chalk) was different from the "coastal Hesse" (which lies on Purple).

If we ask why such a neat and satisfactory solution has never been proved before, the answer must be that the wrong people have been looking at it. Madgett is a pedologist, who has brought a pedological

eye to the examination of that part of the succession which geologists usually dismiss in their field note-books as "Soil 2 m". The story of the Hesse Till shows how dangerous it is for geologists to draw conclusions about superficial deposits without taking pedological advice (as indeed it would be for a pedologist to interpret a soil profile without an understanding of the geological history of the area). In several countries it is now normal practice for Pleistocene sections to be examined simultaneously by geologist and pedologist, who write it up together, in Britain we are moving toward this more integrated approach, largely due to the activities of interdisciplinary groups such as the Quaternary Research Association, but it is still true to say that much more could be done (and mistakes avoided) by a greater awareness in each group of what the other can contribute.

Clearly, as Madgett suggests, the term Hesse Till should now be dropped. Hesse has never been a good type locality, and if the till there is really weathered Drab, there is no point in perpetuating the name. Perhaps these discoveries will stimulate a more comprehensive revision of the nomenclature of the east coast tills. Are "Drab" and "Purple" really satisfactory as stratigraphical names? Is "Hunstanton" any better than "Hesse", if there too the till is weathered Drab? Probably the time has come to redefine them according to modern usage, in which each lithostratigraphical division is "designated by a distinctive proper name and defined in a specified place or region" (*Int geol Correlation Programme*, UK Contribution, Royal Society, 1968).

of our flora and partly as a consequence of the penetrating critique directed at it by Poore (*J Ecol*, 43, 226, 1955). Unconvinced about the real existence of plant communities as definable entities, researchers in Britain and in the United States and Australia have preferred to regard vegetation as a continuum of variation in its specific composition. This being so, the most convenient approach to classification has been the erection of reference points within the continuum at appropriate locations (Poore, *J Ecol*, 44, 28, 1956). As an aid in this task, the tech-

nique of ordination has been used extensively, in essence this involves the comparison of stands of vegetation on the basis of their floristics and the construction of geometrical, spatial models which can best account for the various similarities and differences observed (for example, Bray and Curtis, *Ecol Monogr*, 27, 325, 1957).

Hierarchical classification of stands, reminiscent of the Braun-Blanquet type, has found a place in British plant ecology mainly as a result of the work of Williams and Lambert (*J Ecol*, 47, 83, 1959), who initially used a chi-

square statistic for stand comparison and later an information statistic either for splitting or for agglomerating samples into the most homogeneous groupings possible (Williams, Lambert and Lance, *J Ecol*, **54**, 427, 1966, and Lance and Williams, *Computer J*, **11**, 195, 1968). These methods have provided a degree of objectivity which is not usually a feature of Braun Blanquet classifications, but whether they provide more information to those concerned with community descriptions has often been questioned (see Frenkel and Harrison, *J Biogeogr*, **1**, 27, 1974).

In the United States, Whittaker (*Ecol Monogr*, **23**, 41, 1953) provided a new approach to the classification of vegetation. He plotted stands along axes representing environmental factors, such as moisture availability and altitude. By substituting at each point the abundance of a given species in that stand he was able to ordinate species with respect to their ecological requirements and in this way learn something of the species and consequently of the nature of the community. It is something akin to this approach which Grime has recently used (*Nature*, **250**, 26, 1974) in his analysis of grassland communities, but instead of employing environmental factors as axes he has taken physiological and morphological characteristics of the plants themselves. He uses log maximum relative growth rate on one axis and competitive index (defined in terms of morphology and litter production) on a second axis and is thus able to locate any species in relation to these two parameters. He can substitute vegetation stands for species on such axes by using the mean maximum relative growth rate and mean competitive index of the species found within the vegetation sample. Vegetation from different habitats produces clusters of points in various parts of the graph and Grime accounts for these positionings in terms of stress and disturbance factors. In habitats where stress and disturbance are low, species of high competitive index predominate (see Grime's earlier model of species density variation with environmental stress, *Nature*, **242**, 344, 1973). Species of low competitive index are found mainly in stressed and disturbed habitats, those in the former having generally low growth rates and those in the latter having higher ones. Grime's concept of three major determinants in vegetation composition (that is, stress, disturbance and competition) has led him to use a triangular form in his ordinations.

The usefulness of this new approach to the classification of vegetation will depend upon the validity of this tripartite factor model of plant communities in habitats other than grassland. Is it always possible to

discern between these ill-defined categories of stress and disturbance? Is maximum potential growth rate of a species either an adequate measure of normal growth potential or an adequate criterion for the differentiation of stress- and disturbance-adapted species? We must await data from other habitats. Meanwhile it is refreshing to find a system which steps beyond classification for its own sake and seeks to provide a predictive model upon which management and conservation programmes can be based.

Oceanic lithosphere thickens with age

from Peter J. Smith

At active oceanic ridges there is a regional elevation resulting largely from thermal expansion and perhaps in part from phase changes related to thermal state. Some of the uplift here may also be due to an anomalously thick asthenosphere with an abnormally low density near the ridge crest. But outside the immediate vicinity of the spreading axis, where such arguments no longer apply, the case for variation in lithospheric thickness is much less certain. Most theoretical models of seafloor spreading have therefore assumed that the lithosphere moving away from a ridge has a constant thickness.

Experimentally, the range of determined lithospheric thickness is wide, although most values lie between 40 km and 110 km. For example, upper mantle sections derived from surface wave dispersion observations suggest that an oceanic plate is 70 km thick on average, but other estimates of the same quantity range from 40 km to 100 km. For continental regions there are recorded thicknesses up to 100 km in tectonic belts and up to 150 km in stable shields. Using estimates of the flexural rigidity of the lithosphere, Walcott (*J geophys Res*, **75**, 3941, 1970) calculated the thickness of the normal continental lithosphere to be 110 km and that of the oceanic lithosphere to be 75 km or more. Magnetotelluric methods, on the other hand, have given 10 km thickness for the zone of spreading on Iceland and 40 km for the subduction zone below Kamchatka, the latter value having been confirmed by studies of the attenuation of shear waves.

In short, although existing experimental data probably give lithospheric thickness to the correct order of magnitude, they are far from sufficient for testing whether or not the lithosphere produced at any given ridge has a constant thickness. Moreover, as Vogt (*Earth planet Sci Lett*, **23**, 337, 1974) now points out, there is an inherent

danger in comparing directly determined lithospheric thicknesses insofar as different methods do not necessarily define lithospheric plate in the same way. Rheologically, plate thickness is the maximum depth at which brittle fracture can occur; magmatically, it is the minimum depth at which partial melts are ubiquitous; thermodynamically, it could be defined as the pressure-temperature level at which partial melting begins in a system with known or assumed physical properties, and so on. Not only are these definitions not necessarily identical, the lithosphere-asthenosphere boundary may not even be sharp.

For the time being, therefore, direct experimental determinations are of limited use and recourse must still be made to theoretical models. But the problem with theoretical models involving constant lithospheric thickness is that the thickness is assumed rather than predicted by the model itself. In the important model proposed by McKenzie (*J geophys Res*, **72**, 6261, 1967), for example, lithospheric thickness is a free parameter not determined by the physics, and it was to overcome this difficulty that Parker and Oldenburg (*Nature phys Sci*, **242**, 137, 1973) put forward a modification which enabled them to predict that, beyond 10 km from a ridge axis, the thickness of the lithosphere should increase in proportion to the square root of age.

To test which, if either, view is correct—the traditional assumption or the Parker-Oldenburg prediction—Vogt has adopted and adapted a method first used by Eaton and Murata (*Science*, **132**, 925, 1960) to determine the minimum depth from which magma must rise to reach the summit of Mauna Loa volcano, Hawaii. Eaton and Murata assumed that at the depth of the magma source the magma column exerts the same lithostatic pressure as the surrounding normal crust and upper mantle, including water and sediment (that is, there is isostatic equilibrium). The source depth thus determined was 57 km, and although the calculation was carried out before the days of plate tectonics, this depth agrees with the lithospheric thickness beneath Hawaii obtained by more modern means (for example, from the level of deepest seismicity). Vogt therefore believes that the magma is formed beneath the lithosphere and that what Eaton and Murata were measuring was, in effect, the plate thickness.

It is implicit in this that volcanoes such as Mauna Loa cease activity because of an isostatic limitation and not simply because no further magma is available. If this argument may be applied to most volcanoes, it then follows that there should be an observable relationship between volcano

height and plate thickness, in other words, it should be possible in principle to determine plate thickness indirectly from volcano height. In practice, this will only be possible for active or recently extinct volcanoes because older volcanoes will have been eroded and their heights lost for ever. Moreover, there are almost certainly bound to be some volcanoes which cease activity because of insufficient magma and others that have not yet reached their full height, and in these cases heights will also be too low to conform with any volcano height-plate thickness relationship.

But what do the data show? From the mathematics of the isostatic system, Vogt concludes that, when corrected for the buoyancy of their submerged bases, the height of young oceanic volcanoes should vary as the square root of crustal age. A plot of the relevant observations confirms this relationship with a surprisingly low scatter of points about the straight line. Because the data obey the expected relationship, they implicitly support the assumptions upon which the relationship was derived. In other words, the results suggest that most volcano heights are indeed limited by isostasy rather than magma shortage. An increase in volcano height thus implies an increase in plate thickness, and a linear relationship between volcano height and the square root of age implies a similar relationship between plate thickness and square root of age. Hence there is support here for the Parker-Oldenburg model.

On the other hand, this does not mean that the constant thickness hypothesis may be dismissed without further consideration. For if plate thickness remains constant with age, the average plate density will increase with age, and this will also affect the height to which a volcano may grow according to isostasy. Vogt shows, however, that the height-age relationship expected in this case is quite unlike that actually observed.

Pulsing X-ray stars

from James Pringle

OF the sixty or so X-ray stars known in our Galaxy and in the Magellanic Clouds only a few have so far been found to pulse regularly. One, the Crab pulsar, has a pulse period of 33 milliseconds, as do its radio and optical counterparts, and is thought to be a rapidly spinning neutron star. The star's large energy output, several thousand times that of the Sun, derives from its rotational kinetic energy, the pulse period is observed to increase on a time scale of about a thousand years.

Another two, Centaurus X-3 and Hercules X-1, pulse with periods of 4.84 and 1.24 seconds respectively, but, although their X-ray luminosities are similar to that of the Crab pulsar, their pulse periods vary somewhat irregularly with no great evidence for overall speeding up or slowing down. Both these sources of X-rays are identified with optical stars. It is almost certain that the X-rays originate from a compact companion star, too faint to be visible optically, and that mass transfer from the 'normal' star on to its companion provides the source of energy. One strong possibility is that the compact star is a neutron star with a strong magnetic field (about 10^{12} Gauss). Material falling on to such an object glides along the field lines on to the magnetic poles where it yields about 10% of its rest mass energy on striking the stellar surface. The necessary quantity of energy released in such a small area must lead to high enough temperatures to provide X-ray emission. Rotation of the star, with its two X-ray hot spots, provides the pulse. Radiation produced in such a strong magnetic field should be highly polarised—an important observational test of this hypothesis.

An alternative possibility is that the compact object is a pulsating white dwarf star. For a neutron star, the gravitational energy released by the infall greatly exceeds the nuclear energy released by subsequent hydrogen burning. For a white dwarf of a solar mass, hydrogen burning releases 20 times as much energy as the infall, and even more for less massive stars. It has been suggested that this hydrogen burning could feed energy into pulsations of the star, these would then dissipate through shock waves in the stellar atmosphere. Preliminary work suggested that it was indeed possible to heat the white dwarf's atmosphere sufficiently to provide X-rays of sufficient energy and intensity. But in a recent, and more detailed, calculation, Katz and Salpeter (*Astrophysical Journal*, **193**, 429-436, 1974) conclude that these previous results were too optimistic and that any realistic calculation will give X-ray emission too low by many orders of magnitude.

The authors consider radial pulsations of the star which, at a specified layer below the photosphere, are assumed to be sinusoidal in velocity. They stress that the peak downward acceleration of such a motion cannot be taken to be greater than the effective surface gravity: this condition has been violated in previous work. Also, because in general the scale height in the atmosphere is much less than the radius of the star, there is an 'acoustic mismatch' (and thus a very weak coupling) between the low stellar eigen-

modes and atmospheric sound waves or shock waves. This mismatch can only be avoided if the luminosity of the star is close to the Eddington limit, in which case radiation pressure almost balances gravity and the atmospheric scale height is comparable with the stellar radius. In this event, however, the inverse Compton cooling (the sharing of energy between photons and electrons in the stellar atmosphere) produced by the stellar luminosity becomes most severe, and the shock heating of the atmosphere is suppressed. Compton cooling has been ignored in previous work and the present authors find it to be very important in damping atmospheric shock waves and removing energy from any shock heated material. These effects strongly inhibit the conversion of stellar oscillatory motion into multi-keV X-rays.

The relevance of the above constraints to the non-pulsing X-ray sources is as yet unclear, although the authors do indicate some misgivings about the white dwarf hypothesis as a whole. On the other hand, there has been a tendency among theorists to ignore the possibility of X-ray emission from white dwarfs and it is likely that further progress will be made in this field before very long.

Giant multipole resonances

from P. E. Hodgson

MANY years ago it was found that the cross sections for the radiative capture of protons by nuclei showed broad maxima at energies around 10 to 20 MeV. These persist throughout the periodic table, and accurate measurements showed that the energies of these states is given approximately by $63A^{-1/3}$ MeV.

Goldhaber and Teller (*Phys. Rev.*, **74**, 1046, 1948) explained these resonances as due to collective oscillations of the neutrons against the protons. This accounted both for their universal character and qualitatively for the variation of their energies from nucleus to nucleus. Subsequently a more detailed microscopic theory interpreted them as a quantum-mechanical superposition of particle-hole excitations giving a resonance of an E1 dipole character (Brown and Bolsterli, *Phys. Rev. Lett.*, **3**, 472, 1959; Elliott and Flowers, *Proc. R. Soc.*, **242**, 57, 1957).

Subsequently these dipole resonances were found to be excited in many other reactions, particularly by the inelastic scattering of electrons and protons (*Nature*, **246**, 250, 1973), and detailed analyses of these data allowed many of the properties of the resonances to be determined.

The identification of giant E1 dipole resonances naturally raises the question of the existence of other multipole resonances in nuclei, and over recent years the evidence for some of these has become more convincing. A giant quadrupole resonance several MeV below the giant dipole resonance was found by (e,e') experiments at Darmstadt (Pitthan and Walcher, *Phys Lett*, **36B**, 563, 1971) and confirmed by (p, p') analyses at Oak Ridge (Lewis, *Phys Rev Lett*, **29**, 1257, 1972). Further work at Sendai University (Fukada and Torizuka, *Phys Rev Lett*, **29**, 1109, 1972; Nagao and Torizuka, *Phys Rev Lett*, **30**, 1068, 1973) resolved the new resonance into three separate states, and also provided evidence for other resonances at 19 MeV (E3) and 22 MeV (E2) in ^{208}Pb .

The widths of all these resonances are subject to sum rules analogous to the Thomas-Reiche-Kuhn sum rule in atomic spectroscopy, and it was found that these resonances exhaust a large fraction of the appropriate sum rule, confirming their giant resonance character.

The analyses of proton inelastic scattering by von Geramb and colleagues (*Nucl Phys*, **A199**, 545, 1973) has provided particularly elegant and continuing evidence for some of the higher resonances. Fig 1 shows some of their results. This work enables the apparently irregular behaviour of the inelastic proton scattering at back angles from ^{12}C and ^{16}O to be accounted for, and also gives the parameters of several higher order resonances.

Fig 1 Multipole resonances in ^{16}O found from analysis of proton inelastic scattering. The numbers in squares and the values of λ are the multiplicities.

All this work has recently been strikingly confirmed by recent measurements of the inelastic scattering of 90 MeV electrons by lead and gold carried out by Pitthan and colleagues at Monterey (*Phys Rev Lett*, **33**, 849, 1974). Some of their results are shown in Fig 2, and it is clear that the electron energy spectrum has a definite structure that can be

Fig 2 Spectrum of electrons after inelastic scattering at 75° from ^{208}Pb and ^{197}Au , after subtraction of background. The spectrum is analysed into the components due to the different contributing giant multipole resonances.

analysed into a number of separate components. The energies and widths of these resonances are given in Table 1, together with their multiplicities and whether they are isoscalar ($\Delta T = 0$) or isovector ($\Delta T = 1$), where T is the total isospin. It is notable that the widths of the resonances in ^{197}Au are significantly greater than the widths of the corresponding resonances in ^{208}Pb , this is to be expected since ^{197}Au becomes dynamically deformed when excited, whereas ^{208}Pb remains spherical.

Of the resonances in the table, the E2 resonance at 10.8 MeV is the familiar dipole resonance. The E3 and E2 resonances at 18 and 23 MeV respectively correspond to those found by the Sendai group.

The lowest E1, E2 and E3 resonances are probably the same as those found by von Geramb and colleagues, the widths are very similar although the energies are shifted somewhat, probably due to a different dependence on A through the periodic table. A distorted wave analysis confirms the E0 character of the resonance observed at 9.2 MeV. This is the first experimental indication of a giant monopole resonance and should make possible a determination of the nuclear compressibility. This identification is supported by evidence from (γ, n) spectra. The resonance at 33 MeV is new and the angular distribution for Au has an E0 (or possibly E2) character. This resonance might be the isovector monopole state proposed by Bohr and Mottelson (*Nuclear Structure*, vol 2, 1972), but an accurate assignment is difficult.

Table 1 Characteristics of the giant multipole resonances found from analyses of inelastic scattering of 90 MeV electrons by ^{197}Au and ^{208}Pb .

$E_x A^{1/3}$	EL	ΔT	^{197}Au		^{208}Pb

Persistent superfluid flow

from P V E McClintock

In a recent communication to *Physical Review Letters* (**33**, 1073, 1974), Gal-kiewicz and Hallock report the first really satisfying demonstration of a persistent superfluid current in a helium film. In their experiment, which was carried out at the Amherst campus of the University of Massachusetts, they started the ^4He film moving at a velocity of about 5 cm s^{-1} around a closed path some 40 cm in length, and were then able to show that the energy of flow did not measurably diminish over a period of several hours.

Like other liquids, helium tends to form a thin film up the walls of the vessel which contains it, held in place by the Van der Waals attractive force between the helium atoms and the atoms of the wall. In contrast to other liquids, however, whose films usually evaporate a short distance above the free surface and which are constrained by viscous forces to move at very small velocities, the helium film can indulge in superflow, that is, it can flow at several cm s^{-1} without any dissipation of its energy of flow. Thus, any evaporation of the film is quickly replaced by superflow from the bulk liquid. All surfaces in contact with superfluid helium will therefore be completely covered with a relatively thick (typically 200 Å) film of helium. It is superflow in the film which is responsible for the well known and dramatic phenomenon of the beaker of helium which empties itself while remaining upright; the liquid simply syphons itself out through the channel provided by the film.

The non-dissipative nature of film flow has been fairly convincingly established by experiments where a flow from one vessel to another was maintained without any measurable driving force. Yet, apart from some interesting work in compressed powders and other porous media, no previous attempt to set up a persistent flow of the film around a closed path has been successful.

The most impressive of these earlier investigations was probably that of Wang and Rudnick of the University of California at Los Angeles, described in the recently published *Proceedings of the 13th International Conference on Low Temperature Physics* (edit by K. D. Timmerhaus *et al.*, vol 1, 239, Plenum Press, 1974). Their substrate consisted of a glass cylinder which could be rotated, and they arranged to be able to measure the times of flight around the cylinder of surface waves on the adsorbed helium films (known as third sound) either with or against

the expected persistent current. The velocities of third sound relative to the substrate in the two directions would have been different in the presence of a persistent flow, but no such phenomenon was observed during a series of very careful experiments. In fact, the authors concluded that any such flow, if it existed, was occurring at velocity of less than 1 cm s^{-1} .

In the Amherst experiment both the geometry and the method of initiating the film superflow were entirely different. Rather than on the outside of a cylinder, the film was made to flow along the inside of a 37 cm length of 1.37 mm diameter stainless steel tube, closed on itself so as to form a continuous loop. Also connected to the loop, by separate short copper tubes, were the annular spaces in two pairs of coaxial cylinder capacitors, c_1 and c_2 . On the 12 cm length of the loop between these two connections was wound a heater which, when energised, evaporated the film and prevented it flowing past that point, thus acting as a sort of switch for the superflow. At the beginning of an experiment c_1 and c_2 were partly filled with superfluid helium so that the tubes above them and the stainless steel loop were covered with the film. In coming to equilibrium the liquid levels were, of course, equalised by film superflow. By measuring the capacities of c_1 and c_2 it was possible to determine to a very high precision the amount of dielectric, and thus the level of the liquid helium inside each of them.

To initiate film flow, the heater was energised and a d.c. voltage was applied for a short while across c_2 . The immediate result was a flow of the film out of c_1 , around almost all of the stainless steel loop (except, of course, the short length between c_1 and c_2 which incorporated the heater), and into c_2 . A well known property of film flow between reservoirs is the tendency to overshoot when the levels equalise, resulting in slowly damped oscillations with a period of several seconds. Thus, the disturbance of the levels in c_1 and c_2 was followed by an oscillatory flow between them through the connecting helium film. By de-energising the heater at an appropriate moment the loop circuit was completed for superflow and, though the level oscillations gradually decayed away, it was hoped that a persistent current might be left in the loop.

To test for the presence of a persistent current after a lapse of time, the heater was again energised, thus opening the loop circuit, so that any kinetic energy flow in the film would have to go into depressing the level in the capacitor on the upstream side of the heater and therefore exciting oscillations once more. In practice level

oscillations did indeed occur, even after a lapse of as long as seven hours, and the amplitude of the oscillations did not vary to a measurable extent with the waiting time. The implication must be that Galkiewicz and Hallock had succeeded for the first time in setting up a persistent state of flow around the loop, quite analogous to the persistent electrical current which can be set up in a closed circuit of superconductor in each case there is a macroscopic flow of particles which apparently persists indefinitely without any dissipation of energy.

Why, on the other hand, was Wang and Rudnick's carefully designed experiment a failure? The reason is not yet known but, on the basis of the present experiment, it is unlikely to be connected with momentum exchange between the flowing film and the helium vapour with which it is in dynamic equilibrium, as had been suggested earlier. This same situation also pertained in the successful Amherst experiment. It is to be hoped that further developments of Galkiewicz and Hallock's new technique will yield the answer to this and other problems connected with film superfluidity.

Changes in enzyme activity during plant photomorphogenesis

from our Plant Cell Physiology Correspondent

PROFOUND changes in the activity of many plant enzymes occur during photomorphogenesis, the response of dark-grown plants to light. Most changes are brought about by red or far-red light acting through the phytochrome system, in some instances a photoreceptor absorbing blue light is involved. Typically the activity of enzymes already present in dark-grown plant tissue is stimulated above the basal level within hours. Although other phytochrome-controlled responses occur more rapidly, this system is very convenient for studying the regulation of enzyme activity during plant development. Using the density-labelling technique several groups have obtained evidence suggesting that at least two mechanisms are involved—*de novo* enzyme synthesis and the activation of pre-existing inactive enzymes.

The essence of the density-labelling technique is simple. In order to test whether an increase in enzyme activity in response to a given stimulus is due to synthesis, a heavy isotope such as ^{18}O , ^3H or ^{15}N is briefly supplied to the

tissue at the same time as the stimulus. A protein extract is later prepared from the tissue and fractionated by buoyant density in CsCl using an ultracentrifuge. If the degree of labelling of the enzyme being studied is significantly greater in the stimulated tissue than in control tissue this indicates an enhanced rate of *de novo* synthesis.

Attridge, Johnson and Smith (*Biochim Biophys Acta*, **343**, 440, 1974) have studied the phytochrome-controlled increase in activity of phenylalanine ammonia-lyase (PAL) in mustard cotyledons. They have shown, using $^3\text{H}_2\text{O}$, that PAL and acid phosphatase become density labelled in cotyledons of both irradiated and dark-grown plants, indicating that enzyme synthesis is taking place in all cases. The degree of density labelling of acid phosphatase is unaffected by irradiation, whereas if PAL labelling is measured during the time that the enzyme activity increases in response to light the density labelling of the enzyme is actually lower than in dark grown plants. The authors suggest that the increase in enzyme activity detected in the light is due to the activation of previously synthesised enzyme, although a decrease in the rate of degradation of the enzyme could also be involved. Similar results were obtained for the blue-light controlled increase in PAL activity in gherkin hypocotyls (Attridge and Smith, *Biochim Biophys Acta*, **343**, 452, 1974) and the authors cite evidence for the presence of a substance in this tissue which reversibly inactivates PAL.

Another enzyme that increases in activity in irradiated mustard cotyledons is ascorbic acid oxidase. Attridge (*Biochim Biophys Acta*, **362**, 258, 1974) has shown that when dark-grown plants are transferred to $^3\text{H}_2\text{O}$ and irradiated with far-red light, the density of the enzyme increases to the maximum observed within six hours (much more rapidly than the dark control). This evidence strongly suggests that ascorbic acid oxidase, unlike PAL, is synthesised more rapidly in response to light. Increased ribonuclease activity in lupin hypocotyls also seems to be due to phytochrome-controlled stimulation of enzyme synthesis according to Acton and Schopfer (*Biochem J*, **142**, 449, 1974). These workers were able to demonstrate a greater increase in density of the enzyme in illuminated plants compared to the dark-grown controls. Band-broadening of the enzyme peak in CsCl also provided evidence for the presence of a population of differently deuterated enzyme molecules—to be expected if the density marker takes a significant time to equilibrate with the amino acid pool. The regulatory mechanisms governing the synthesis of these enzymes remain to be determined.

Earliest record of man's presence in Britain

M. J. Bishop

Department of Geology, University College London, Gower Street, London WC1E 6BT, UK

Middle Pleistocene deposits near Westbury-sub-Mendip have yielded flints which pose problems in the local geological context. Some of the flints show signs of having been worked by man and as such they may be artefacts. The flint-bearing layers contain a rich mammalian fauna of Cromerian age, which suggests that the artefacts may mark the earliest record to date (~400,000–500,000 yr BP) of man's presence in Britain.

WORKED flints have been recovered from cave sediments of late Cromerian age near Westbury-sub-Mendip, Somerset. The deposits, which may provide the earliest record yet of man's presence in the British Isles were first noticed in 1969 (see refs 1 and 2). They are exposed in a working Carboniferous Limestone quarry (ref IT 506504) between 213 m (700 feet) and 244 m (800 feet) or on the southern plateau edge of the Mendip Hills. They infill, to ground level, what is believed to be part of a former cairn system. The present exposure, in the unworked northern face of the quarry, is 90 m wide, and nearly 30 m high.

Stratigraphy

The main stratified sequence¹ (Fig. 1) is no longer visible, and much of it has been blated out in the interests of safety and has been lost forever. The beds were well stratified and about 10 main layers, grouped into two main divisions, could be distinguished, in which three separate mammal faunas have been recognised (Table 1).

The sands and gravels of the Siliceous Group (Table 1) are waterlaid deposits, comprising material that is largely foreign to the area. Rare, angular fragments of Carboniferous chert occur, but Carboniferous Limestone, if it was ever present, has been removed by solution. The foreign constituents are thought to be derived from former cover sediments, but no flint has been found in these, which emphasises that the latter is foreign to the overlying Calcareous Group. A sparse mammal fauna has been collected from the gravels and although it is apparently derived it is no earlier than late Lower Pleistocene.

The Calcareous Group comprises conglomerates and breccias made up of rounded to angular fragments of Carboniferous Limestone, with variously coloured matrices of silt and clay. Well stratified horizons occur only in the central area of the infill, and these yield both the flint and the richest remains of large fossil mammals. The bulk of the mammal finds have so far come from beds 3, 4 and 5 (Fig. 1), which are regarded as downwash accumulations from a former, upstream 'den'. Unfortunately, it is this valuable stratigraphical sequence which has been destroyed. Laterally to the west of this sequence is the Roent Earth (Table 1) and on the east side is an extensive sequence of breccia deposits which are

rich in fossil mammal material, but which have not yielded flints so far.

Most of the rock constituents of the Calcareous Group are Carboniferous Limestone, though there are indications that some of the limestone is not local, but has been transported into the infill from the surrounding district. The only other rock types in this group are the flints, and three rounded pebbles of ironstone, all found in the central stratified sequence of the Calcareous Group.

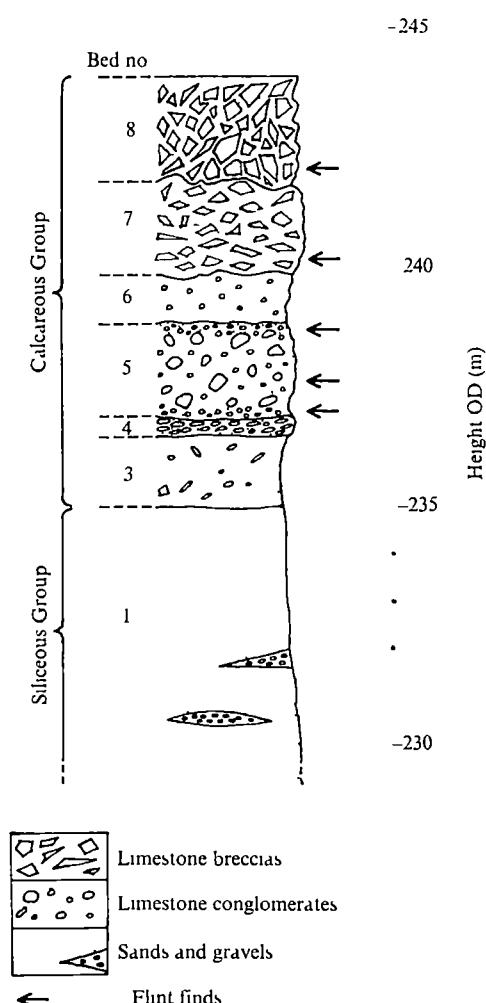

Fig. 1 Stratigraphical section of the upper part of the main layered sequence, visible up to July 1974

Fauna and age

The mammal faunas have been used to date the deposits and experimental radiometric work on stalagmite samples from Westbury is under way (D Ford, personal communication).

The fauna of the Calcareous Group comprises predominantly bear remains, probably all *Ursus deningeri* Reichenau, the bones and teeth of which represent individuals of all ages, indicating that the species was a resident of the area. Shelter was probably available in a former upstream, cavern area, which provided a den for bears and occasional living quarters for other hunting animals. A large proportion of other carnivores which are of Cromerian aspect are represented in this fauna, of which the small wolf *Canis lupus mosbachensis* Soergel is very common. Remains of the sabre-toothed cat *Homotherium latidens* Owen, have been found in a number of horizons, and the first British occurrence of the extinct dhole *Xenocyon lycaonoides* Kretzoi, and the 'European jaguar' *Felis gombaszoegensis* Kretzoi, are recorded here. Herbivores form a proportionately small part of this fauna, but they include the rhinoceros *Dicerorhinus etruscus* Falconer which is an important faunal element in indicating a Cromerian age.

Few mammal remains have been collected from bed 8 mainly because it is not easily accessible. The contemporary Rodent Earth is physically separate from the main outcrop of the Calcareous Group, but apparently belongs to it on the basis of its fauna. The fauna of the Rodent Earth comprises predominantly small mammals, most of which are voles, *Pitymys gregaloides* Hinton being the most common. The first British occurrence of the vole *Phomys episcopalus* Méhely is recorded here. Both of these species indicate that this fauna is pre-Holsteinian (pre-Hoxnian). The abundance of *Arvicola cantiana* Hinton and absence of *Mimomys*, suggests strongly, however, that this fauna is later than the Upper Freshwater Bed of West Runton³ (Cromerian Zone II⁴), as *Mimomys* is believed to be the direct ancestor of *Arvicola*^{5,6}.

Table 1 Main divisions of the early Middle Pleistocene sequence

Calcareous Group (cave conglomerates and breccias)	Rodent Earth Fauna
Siliceous Group (waterlaid sands, silts and gravels)	Calcareous Group Fauna
	Siliceous Group Fauna

The faunas of the Calcareous Group and the Rodent Earth correlate well with the European sites at Mosbach, Mauer, Hundsheim and Tarko, which are usually considered to be between Cromerian (*sensu stricto*) and Elsterian in age. Correlation with the type Cromerian of the Cromer Forest Bed Series³ is difficult because most of the mammalian material of the type area was collected in the nineteenth century, and records of localities and stratigraphical position are often lacking. There are, however, good records from the West Runton Upper Freshwater Bed⁴. By comparison, the Westbury faunas seem to be younger, and for this reason are here termed 'late Cromerian'. It is possible that they are of about the same age as the younger fauna from Ostend, near Bacton⁴, as *Arvicola cantiana* is common to both sites. Koenigswald⁶ regards the faunas from Mosbach, Mauer, Hundsheim and Tarko as later than the Upper Freshwater Bed but earlier than Holsteinian (Hoxnian). It would seem that these sites, and the Westbury site as well, show clear faunal distinctions from the Holsteinian, and to some extent from the Cromerian (*sensu stricto*), yet these faunas are themselves temperate. It may be that they are separated from the Cromerian (*sensu stricto*) by a climatic barrier such as a cold phase, or a fully glacial phase (see ref 7). Preliminary palynological data (R N L B Hubbard, personal communication) on a Westbury sample from the level of bed 4, indicates that this is zone II of an interglacial. It is hoped that future work on the palynology, fauna

and sedimentology will elucidate the problem of whether a previously unrecognised temperate age is represented in Britain between the Cromerian (*sensu stricto*) and the Hoxnian.

Flints

Flints occur at five horizons within the Calcareous Group (Fig 1). The flint is white and usually rotted, often to the extent that it breaks down easily to fine powder. It is non-calcareous, shows conchoidally fractured faces, and contains

Fig 2 a, struck flake, from bed 5, b, rude bifacial flint from bed 5, worked from a flattened pebble, c, Ovate, bifacial worked flint from bed 8

Upper Cretaceous foraminifera. It occurs most commonly as angular or subangular pieces up to cm in size, in bed 5 they occurred as frequently as one in every 8,000 cm³. Sizes between 3 cm and 9 cm are rare (Fig 1). Despite the chemical breakdown in most of the flints, the larger specimens are well preserved and show few signs of rounding. Even under microscopic examination the ridges between the flake scars are sharp and fresh, indicating that the flints have not travelled far. Only around the leading edges of the large flints do signs of wear and abraded occur.

Five of the flints show apparent signs of human workmanship. The oldest two are from bed 5, one is a flake (Fig 2a) and the other is a small bifacial implement (Fig 2b) which retains part of the original surface of the flattish pebble from which it was fashioned. The largest and most diagnostic implement (Fig 2c) is from bed 8, it is thick bifacially worked ovate. The two bifacially worked pieces of flint (Figs 2b and c) are probably Acheulian (K P Oakley, personal communication). As the associated fauna has been identified as Cromerian, these implements must rank among the earliest Acheulian artefacts known in Britain, presumably comparable with the so-called Abbevillian in the 45 m terraces of the Somme (K P Oakley, personal communication). The preservation of the flints, and the fact that sediment samples (from the level of bed 4) broken down for pollen, contained abundant microscopic charcoal fragments (Hubbard, personal communication), indicate that an occupation site may have existed in the former cavern area.

The new finds at Westbury support suggestions⁸ of an early date for the worked flints from the basal breccia at Kent's Cavern, Torquay⁸, because it is now clear that man was present in southern Britain much earlier than had been supposed. Unfortunately, the mammal fauna from these basal breccias is too poorly known at present to allow reliable correlation with the Westbury deposits, though the presence of *Arvicola*

and *Pitymys gregaloides* at both sites is highly suggestive of such a correlation

The earliest occupation sites in Europe have, from a consideration of their mammal faunas, been described broadly as Cromerian⁹. Those with good artefactual evidence, within a well defined stratigraphy, and with good faunal associations are extremely rare, they include, however, Vértesszölös in Hungary (considered to be Elsterian in age), and Vallonnet in France⁹. Although Westbury does not seem to represent the immediate area of an occupation, there is evidence that an occupation site may have existed very close to the present location of the artefacts. This, and the fact that Westbury displayed a very well defined stratigraphy with very rich and abundant faunal associations, ranks Westbury among the most important Pleistocene sites in Europe with evidence of man.

Although the valuable flint bearing strata have been blasted

away, it is hoped that more finds will be made by examining all of the fallen material, new flint bearing layers may become exposed as a result of future excavations.

I thank Westbury Quarry (Mixconcrete Aggregates Ltd) for permission to study deposits in the quarry, and Professor D T Donovan, Dr J E Robinson and Dr A J Sutcliffe for criticism. I thank Miss M O Miller (British Museum) for drawing the flints.

Birefringence experiments on isolated skeletal muscle fibres suggest a possible signal from the sarcoplasmic reticulum

S. M. Baylor & H. Oetliker*

Department of Physiology, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06510

When stimulated by external electrodes, a frog muscle fibre bathed in hypertonic Ringer gives a birefringence signal consisting of three components. The small first component is due to the action potential of the surface membrane, and the much larger second component may be related to voltage change across the sarcoplasmic reticulum associated with the release of Ca²⁺. The third component is of uncertain origin.

SEVERAL investigators^{1–8} have described light signals which can be detected during the twitch of vertebrate skeletal muscle. These signals are usually measured as changes in light intensity, but depend on various optical mechanisms, including absorption and/or scattering^{1–5}, fluorescence^{4,6} and birefringence^{4,7,8}. In the hope of learning more about the very early events underlying the activation of contraction, we have carried out birefringence experiments on single muscle cells. The major problem in optical experiments on excitable tissue is often not so much to find light signals but to identify as precisely as possible the subcellular events which cause them. So far this effort has been less successful in muscle than in nerve.

Cohen *et al.*⁹, in birefringence experiments on the squid giant axon, showed that signal averaging techniques could detect a small decrease in light intensity coincident with the action potential. This signal had a peak size of about 1×10^{-5} (maximum change in light intensity during the spike divided by resting light intensity). Voltage clamp experiments¹⁰ provided good evidence that the birefringence signal was principally related to potential change across the surface membrane, and showed that the light signal followed the voltage change with a time constant of tens of microseconds.

Unlike nerve, a skeletal muscle fibre has in addition to the surface membrane two well developed membrane systems

thought to be important in the activation of contraction. These are (1) the transverse tubular membranes (T-system), which has in frog sartorius muscle 5–10 times as much membrane area as the surface^{11,12}, and (2) the sarcoplasmic reticulum (SR), which has in frog 75–150 times as much membrane area as the surface¹¹. The physiological roles of these membrane systems are, in outline, fairly well understood. The action potential on the surface membrane depolarises the T-system within the fibre^{13,14}, which in turn triggers the release of Ca²⁺ into the myoplasm from its internal storage site, the sarcoplasmic reticulum¹⁵. The increased myoplasmic Ca²⁺ concentration then activates the contractile proteins¹⁶.

If the membrane systems of muscle, like the squid giant axon, give birefringence signals dependent on membrane potential, these signals might be considerably larger in muscle, because of the greater quantity of membrane involved. Carnay and Barry⁴, in birefringence experiments on muscle bundles of about 50 fibres, found a relatively large decrease in light intensity (peak size about 2×10^{-4}) beginning coincident with the extracellularly recorded action potential. As this signal was about 20 times larger than that for the action potential in squid, it seems unlikely that all of it can be attributed directly to depolarisation of the surface membrane. Because all fibres in a bundle or whole muscle will not give the same signal at the same time, we decided to study muscle birefringence signals using the isolated single fibre preparation.

Single fibres from the semi-tendinosus or ilio-fibularis muscles of frogs (*Rana temporaria*) were isolated and stretched around a small vertical glass post, to minimise vibrational motion and hence optical noise, in a glass-bottomed Perspex chamber. One tendon end was attached to the arm of an RCA 5734 mechano-electric transducer for monitoring isometric tension. The chamber was then mounted on the stage of a Reichert Zetopan polarising microscope with a $\times 40$ water-immersion lens (Zeiss, N.A. 0.75) for optically recording from a 500 μ m length of the fibre. Two platinum wire electrodes brought close to the fibre delivered the stimulus pulse (duration 0.2–0.5 ms).

*Present address: Physiologisches Institut der Universität Bern, Buhlplatz 5, 3012 Bern.

Only those fibres giving an all-or-nothing response to external stimulation were used for experimentation. The illuminating light, from a 100 W FCR tungsten-halogen bulb, traversed a heat filter and two plane polarisers, one preceding and one following the fibre in the light path. To maximise the size of birefringence signals from subcellular structures with optical axes either parallel or perpendicular to the fibre axis, one polariser was oriented at -45° and the other at $+45^\circ$ with respect to the fibre axis. The light detector, a PV-100 photodiode (EG & G Inc.), produced an output current that was a linear function of light intensity transmitted by the second polariser. This output was converted to a voltage signal by means of a conventional operational amplifier circuit, amplified by a 3A9 amplifier in a Tektronix 565 oscilloscope and fed to one of two signal averaging computers, CAT model 1000 (Technical Measurement Corp.) or Nicolet 1072 (Nicolet Instrument Corp.). The response of the light-recording system to a step of light was 70% complete within 80 μ s. A standard Ringer solution was used: 120 mM NaCl, 2.5 mM KCl, 1.8 mM CaCl_2 , buffered with 2.15 mM Na_2HPO_4 and 0.85 mM NaH_2PO_4 to a pH of 7.1 (ref. 17). For many experiments the Ringer was made hypertonic (see below) by increasing the concentration of NaCl. The temperature for most experiments was between 19° and 24° C. In voltage-recording and current-passing experiments, glass microelectrodes with a right-angle bend to fit under the microscope objective were used, in order that the optical signal could be recorded simultaneously with intracellular electrical measurements.

Birefringence signal without fibre movement

During a twitch in normal Ringer, gross movement of the fibre gives rise to very large optical signals, of the order of 10^{-2} even in highly stretched fibres. Bathing a fibre in 2.2T hypertonic Ringer (2.2 times the standard tonicity), however, greatly reduces or eliminates fibre movement while the surface membrane still gives normal or nearly normal action potentials¹⁸. In fibres in which 2.2T hypertonic Ringer reduced the twitch tension response essentially to zero, three components of the optical signal were usually seen, as Figs 1 and

Fig. 1 Three-component birefringence signal in response to external stimulation from a muscle fibre in 2.2T hypertonic Ringer (270 mM NaCl). The trace is an average of 100 all-or-nothing responses. The peaks of the three components are labelled, the first component begins after a small conduction delay following the stimulus artifact (arrow). The vertical calibration gives the ratio of the change in light intensity to the resting light intensity, normalised with respect to a single sweep. A deflection in the downward direction represents a decrease in light intensity. Optical signal d c coupled, optical recording 2 mm from the stimulus cathode, fibre diameter 85 μ m.

Fig. 2 *a*, Optical recordings from the same fibre in Ringer solutions of various tonicities superimposed by lining up the stimulus artifact (arrow). 1T, 120 mM NaCl, 2.2T, 270 mM NaCl, 2.6T, 320 mM NaCl, 3T, 370 mM NaCl Ringer. Each tracing is the average of 64 sweeps, which were taken in the order of increasing tonicities. Following the record in 3T Ringer, the fibre still gave an all-or-nothing response when returned to normal Ringer, with its average for 64 sweeps falling between the 1T and 2.2T tracings shown. Optical recording 1.5 mm from stimulus cathode, optical signal a c coupled, fibre diameter 85 μ m. *b*, Optical (o) and intracellular voltage (v) recordings taken simultaneously in 3T Ringer (370 mM NaCl). The optical tracing has been inverted and scaled to facilitate comparison with the action potential. The upper vertical calibration refers to the optical trace and the lower to the potential trace, each of which is an average of 300 sweeps. Resting potential of the fibre varied between -70 at the beginning of the average to -65 at the end. In agreement with results reported by others, we found that strongly hypertonic solutions tended to depolarise the fibres. Fibre diameter 65 μ m, 7 mm from the stimulus cathode, optical a c coupled, voltage d c coupled.

3b show (1) a small, early shoulder which occurred just as the optical trace departed from the baseline and which reached a distinct peak (Fig 1) or a plateau (Fig 3*b*) in 1–2 ms (this component is too small to be distinguished in a single sweep, and in a bundle or whole muscle would probably be difficult to resolve, even with signal averaging, because of differences in conduction velocity among fibres), (2) a relatively large signal, which reached a plateau (Fig 1) or a distinct peak (Fig 3*b*) 5–7 ms after the beginning of the optical signal (large enough to be seen easily in a single sweep), and (3) a more slowly developing signal which reached a peak 15–50 ms after the stimulus. As determined in other experiments in hypertonic Ringer, the first and second components propagate with a velocity appropriate to a muscle action potential at room temperature (about 1.5–2 mm ms⁻¹) and were seen in fibres with a twitch tension response less than 0.3 g cm⁻². These signals were primarily due to a birefringence mechanism, since they could be converted from a decrease in light intensity to an

increase in light intensity by adding an appropriate amount of optical retardation in series with the light path using a compensator⁹

First component

An early shoulder (first component) similar to that of Figs 1 and 3b was usually seen with signal averaging in hypertonic Ringer but only occasionally seen in normal Ringer. An explanation for this is that hypertonicity slows the development of the second component while leaving the first relatively unchanged. Thus the two components become separated in time. This is shown in Fig 2a, in which optical recordings from the same fibre in Ringer solutions of increasing tonicities have been superimposed by lining up the stimulus artefact. In normal Ringer there is an extremely fast departure of the optical trace from the baseline with no evidence of an early shoulder, whereas in 3T Ringer an early signal about 1.6×10^{-5} (peak size) with a time to peak of 1 ms is revealed. In Ringer solutions of intermediate tonicities, the first component is seen at intermediate states of development, before being obscured by the rising phase of the second component.

It is interesting to know the timing of the first component in relation to the surface action potential. This was determined for the fibre of Fig 2b in 3T Ringer by simultaneously recording the optical and intracellular voltage signals for an average of 300 sweeps. The vertical gains have been adjusted to match peak size and the optical trace inverted to facilitate comparison. The two traces superimpose very closely until late in the falling phase of the action potential. It seems reasonable therefore to attribute most of this early distinct signal and the shoulder seen in less hypertonic Ringer to the voltage change across the surface membrane.

Fig 3 a, Current-passing experiment showing the simultaneously recorded optical (o) and intracellular voltage (v) responses in 2.2T Ringer (270 mM NaCl) for an average of 256 sweeps per trace. At the time indicated by the arrow a 20-ms step of inward current was passed across the cell membrane through a second intracellular electrode (current trace not shown). Resting potential of the cell was -80 mV. Fibre diameter $90 \mu\text{m}$, optical a c coupled, voltage d c coupled. b, Three-component signal in response to external stimulation, taken just before the fibre was impaled for the current-passing experiment shown in (a). Optical a c coupled, 8.5 mm from cathode, 64 sweeps. The same time calibration applies to both parts of the Figure.

Fig. 4 Current-passing experiment in 2.2T hypertonic Ringer with TTX added (10^{-8} g ml^{-1}). Voltage (v) and optical (o) responses were simultaneously recorded during (a) a 30 mV hyperpolarising step, (b) a 10 mV depolarising step, and (c) a 30 mV depolarising step. Resting potential was -68 to -66 mV. Fibre diameter $90 \mu\text{m}$, optical a c coupled, voltage d c coupled, 32 sweeps per trace.

Second component

In contrast to the first component, the characteristics of which appear to be relatively independent of tonicity, the appearance of the second component is strongly dependent on tonicity. As the tonicity is raised, time to peak is increased and rate of rise (Fig 2a) and peak size are reduced. For example, the time to peak was often extended to 8 or 10 ms and peak size typically decreased by a factor of 5–10 in going from 2.2T to 3T Ringer. On the other hand, in measurements in normal Ringer directly over the site of action potential initiation, a much larger decrease in light intensity began immediately after the stimulus, occasionally starting with a distinct first component, and reached a plateau or peak 2–5 ms later. In normal Ringer the second component had a peak size of 1.3×10^{-3} , about 50 times larger than the second component seen in 3T Ringer.

Since fibre movement itself is a strongly graded function of tonicity, the question of whether the second component is related to fibre movement should be considered carefully. Clearly the second component is not due to simultaneous movement of the whole fibre, because it propagates with the speed of the action potential. When the Ringer was made sufficiently hypertonic so that twitch movement was essentially eliminated, the second component propagated throughout the fibre. In normal Ringer, however, gross fibre movement begins well before the action potential can propagate over all of the fibre. In this situation the propagating second component became obscured by the movement artefact after travelling some distance from the stimulus cathode. With signal averaging in normal Ringer, latency relaxation (the earliest fibre movement detectable by the 5734 transducer) was seen to begin about 2 ms after the stimulus. By this time the second component recorded

adjacent to the stimulus cathode was near or at its peak in many fibres, which also confirms that the second component is not due to gross fibre movement. The second component therefore reflects a propagating change beginning just after the surface action potential, possibly a step linking excitation to contraction.

To determine what fraction of the second component might be attributable to depolarisation of T-system membranes alone, current-passing experiments of the type illustrated in Fig. 3 were done. Figure 3*a* shows the optical signal resulting from a current-passing experiment on a fibre in 2.2T Ringer. The fibre was impaled with two separate electrodes, one for passing current and one for recording potential. At the time indicated, a step of hyperpolarising current was passed across the cell membrane and the voltage and optical responses were recorded and averaged. Although the signal-to-noise ratio was rather poor because of the small signal and mechanical vibrations arising from the two intracellular electrodes, the resulting optical signal for an 18 mV hyperpolarisation had a peak size of about 1×10^{-5} . Although not convincingly resolved in Fig. 3*a*, the time-course of the optical signal recorded in other experiments giving larger voltage and optical responses followed voltage and not current. Since the current step was sufficiently long to ensure that the potential across the T-tubular membranes was within a few per cent of the surface potential, the optical signal in Fig. 3*a* probably reflects voltage changes across both surface and tubular membranes. On this basis, one would not expect an action potential in the T system, causing a tubular membrane potential change of perhaps 100 mV¹⁹, to produce a decrease in light intensity for this cell larger than about 5 to 6×10^{-5} . Therefore, T-tubular depolarisation alone would explain only a small fraction of this fibre's second component, which had an amplitude of 3.5×10^{-4} in 2.2T Ringer (Fig. 3*b*).

Not all current-passing experiments produced a birefringence signal with the polarity indicated in Fig. 3*a*, the polarity to be expected if T-tubular membrane always gives an optical signal with the same sign as that from the surface membrane. Fibres of larger diameter occasionally gave signals of opposite polarity (a decrease in light intensity in response to hyperpolarising steps and an increase in light intensity in response to small depolarising steps), while the first and second components in response to external stimulation showed the usual decrease in light intensity. Although this phenomenon is not completely understood, the results from the current-passing experiments in both kinds of fibres in both 2.2T and normal Ringer support the conclusion that the mechanism underlying the second component is not primarily potential change across the membranes of the T-system.

To investigate further the optical signal resulting from a controlled change of surface and tubular membrane potential, current-passing experiments were carried out using tetrodotoxin⁶ (TTX) (10^{-6} g ml⁻¹), which eliminates regenerative depolarisation of surface and tubular membranes. Figure 4 shows such an experiment for a fibre in 2.2T hypertonic Ringer. At the lower optical gain used, little or no light signal was seen during a current step in the hyperpolarising direction (Fig. 4*a*) or a small current step in the depolarising direction (Fig. 4*b*). A large birefringence signal developed, however, with a moderate-sized depolarisation into the voltage range where contraction is normally activated (Fig. 4*c*). The highly nonlinear dependence of this signal on membrane potential makes it improbable that the signal can be explained simply in terms of voltage change across surface and T-tubular membranes. In other TTX experiments, using larger depolarising steps of short duration, the optical signal was larger and reached an earlier peak, resembling in size and time course the second component seen in 2.2T Ringer following the action potential. This similarity suggests that the second component is caused by the mechanism that gives rise to the optical signal illustrated in Fig. 4*c*, and therefore that the second component is caused by a mechanism which is strongly regulated by surface or T-tubular membrane potentials in the contractile range.

Second component and sarcoplasmic reticulum

The second component is $3\text{--}5 \times 10^{-4}$ in 2.2T Ringer (about 30 times the size of the optical signal attributed to the surface action potential) and in normal Ringer is 1 to 3×10^{-3} (about 150 times that of the surface action potential). If it originates directly from a membrane potential change, only the sarcoplasmic reticulum would seem to have sufficient membrane area to account for its size. Furthermore, it is reasonable to speculate that there is an SR potential change occurring at the time Ca²⁺ is released to trigger the activation of contraction. For example, if Ca²⁺ release were the result of a Ca²⁺-specific permeability increase in the sarcoplasmic reticulum membrane, the SR might undergo a sizeable potential change within a few ms of the action potential on the surface membrane. During a twitch at room temperature, a muscle fibre typically begins the rapid production of positive tension 3–6 ms after initiation of the action potential. Just before this, a large amount of Ca²⁺ presumably moves across the SR membranes into the myoplasm. Therefore the early timing of the second component, with a time to peak in normal Ringer of 2–5 ms after the surface action potential, is also consistent with the speculation that the second component is signalling an SR potential change associated with the release of Ca²⁺. (The second component is similar in several ways to a fluorescence signal recently found by Bezanilla and Horowitz⁶ in whole frog muscle and also suggested by them to arise from an SR potential change).

Along these lines, a rough estimate can be made of the magnitude of this possible SR potential change, by using the signal from the surface membrane as a calibration. The calculation assumes that for a given quantity of membrane, either in the SR or on the surface, equal changes in light intensity are produced by equal changes in membrane voltage. (This assumption may be approximately correct, in that both membrane systems, considered as subcellular birefringent structures, involve cylinders of membrane extending the width of the fibre and oriented in the direction of the fibre axis.) Experiment has shown that for a range of fibre sizes the factor relating the peak size of the second component (determined in normal Ringer) to the peak size of the first component (determined in hypertonic Ringer) averages about 1.5 times the factor relating the quantity of SR membrane to the quantity of surface membrane. This latter factor has been determined for frog sartorius muscle to be about $2.7a$, where a is fibre radius measured in microns¹¹. The above assumption then implies that the magnitude of the SR potential change may be about 135 mV (1.5 times the surface action potential in 3T Ringer, which is measured to be about 90 mV).

If the ionic current causing this presumed SR potential change was primarily carried by Ca²⁺ moving from one side of the SR to the other, it is interesting to note how much increase in total myoplasmic Ca²⁺ would correspond to a 135 mV potential change. From the quantity of SR membrane found per litre of muscle¹¹ and the relationship $q = CV$, the increase is about 35 μmol of Ca²⁺ per litre of myoplasm. (For this calculation, a capacitance of $1 \mu\text{F cm}^{-2}$, a value typical of many biological membranes, has been assumed.) Because some Ca²⁺ may also cross the SR in addition to that flowing as net ionic current, 35 $\mu\text{mol l}^{-1}$ represents a minimum increase in total myoplasmic Ca²⁺. This roughly calculated quantity is therefore in reasonable agreement with the total Ca²⁺ thought to be released from the SR during a twitch, 100–150 $\mu\text{mol l}^{-1}$ (M. Endo and L. L. Costantin, personal communication). It is unclear why the peak size of the second component is a graded function of tonicity, falling by a factor of about 50 in going from normal Ringer to 3T Ringer. If the above speculation is correct, the observation is of interest since it would suggest that the amount of Ca²⁺ released during the twitch of a vertebrate fibre is a graded function of tonicity.

This work was supported by a grant from the United States National Institutes of Health to Dr W. K. Chandler, whom we thank for support and advice. We also thank Mr H. Fein and

staff (for assistance with design and construction of equipment) and Drs L B Cohen (for loan of equipment and for advice) and R W Tsien (for discussion)

letters to nature

Silicate absorption at 18 μm in two peculiar infrared sources

Two broad emission features often observed in the infrared spectra of cool stars near 10 and 18 μm are commonly attributed to thermal radiation by silicate dust grains¹. This identification is suggested by laboratory analyses of silicate minerals, which indicate strong lattice vibrations resulting from Si-O stretching modes (in the 10- μm region) and Si-O-Si bending modes (near 18 μm). For luminous sources shining through cold, intervening dust clouds which contain silicates, it is expected that both the stretching and bending bands should be observable in absorption (for sufficiently large column densities of dust). The infrared spectrum of the Galactic centre shows a deep absorption feature at 10 μm (N J Woolf, unpublished) and evidence for absorption at 18 μm (ref 2). Strong 10- μm absorption is also observed for the Orion point source 'BN' (ref 3), IRS5/W3 (ref 4), and AFCRL809-2992 (ref 5), no data demonstrating the presence of 18- μm absorption for these sources at longer wavelengths have yet appeared. We report here the detection of 18- μm absorption features in the spectra of AFCRL809-2992 and an infrared object associated with the microwave source OH 26.5+0.6 (ref 6). We attribute these features to the Si-O-Si bending mode in silicates.

The object AFCRL809-2992 is a strong infrared source found in the direction of the Cygnus X radio complex. Molecular line emission from HCN and CS has been detected by Morris *et al*⁷, the weak radio continuum flux of this source (see ref 5) indicates the absence of a compact H II region and places this object in the Class I category⁷. At 10 μm AFCRL809-2992 is apparently point-like (see ref 5). OH 26.5+0.6 is an exceptionally strong OH satellite-line emitter with a radio spectrum which is similar in appearance to that of the Type II OH/IR stars⁶. The near-infrared properties of this source, as well as spectrophotometry of the 10- μm absorption feature, will be reported elsewhere (G Neugebauer, in preparation). Our raster scans of OH 26.5+0.6 indicate that the associated infrared source is point-like at a wavelength of 20 μm .

Multifilter infrared photometry of these two objects was obtained with the 2.24-m telescope of the Mauna Kea Observatory between June and September, 1974. Neither source has an optical counterpart, so we located both by scanning the telescope for peak infrared signal. Standard beam-switching techniques were used, the focal-plane aperture was 13'' and

the beam displacement was 19'' in declination. Observations were made with intermediate bandwidth filters over the spectra range 5-33 μm . At wavelengths between 5 and 20 μm , we used stars which have been observed already^{8,9}, to establish an absolute flux calibration. At 25 μm and 33 μm we normalised to α Boo and α Ori, respectively, the calibration at 33 μm has been discussed in greater detail elsewhere¹⁰.

Our observations are summarised in Fig 1 along with published spectrophotometry of the AFCRL source⁵. The observational uncertainties in the photometry are estimated to be 10% or smaller. Clearly, the spectra of both objects show pronounced absorption features near 10 and 18 μm . Our photometry of the OH source does not delineate sufficiently the 10- μm band to show the deepest (central) part, the observations of the AFCRL source indicate, however, that maximum absorption occurs near 9.8 μm . Similarly, we cannot locate precisely the position of maximum absorption at longer

Fig 1 Observations of two peculiar infrared sources. O, Photometry of OH 26.5+0.6, ●, photometry of AFCRL809-2992, —, spectrophotometry of the AFCRL source from ref 5.

wavelengths, but we infer from the spectrophotometry of the AFCRL source that band centre must lie between 16 and 18 μm (If the position of the band centre actually falls short of about 16.1 μm , then it will be unobservable from the ground because of absorption by the Earth's atmosphere.) The observed positions of the absorption features are in reasonable agreement with the computations of Knacke and Thomson¹¹, which predict that the Si-O stretching band falls between 9.1 and 9.5 μm and that the Si-O-Si bending band lies between 16.7 and 18.5 μm .

An estimate of the optical depth of the 18- μm absorption band of the AFCRL source can be obtained from a model similar to that discussed by Merrill and Soifer⁵, that is, an emitting source, with a spectrum which follows a Planck curve of $T \sim 350$ K, is assumed to lie behind a cold, absorbing dust cloud. If the Planck curve is normalised to the observed fluxes at 5 and 33 μm , at which wavelengths the opacity of the overlying dust is reduced substantially from the peak near 10 μm , then the optical depth of the cloud at 18 μm is ~ 1.0 . The optical depth at 10 μm for this model is approximately 2.6, giving the ratio $\tau_{18 \mu\text{m}}/\tau_{10 \mu\text{m}} \approx 0.38$. Although the derived optical thickness of the cloud depends on the source spectrum adopted, the opacity ratio is somewhat less sensitive to this assumption. For example, if a smooth curve is drawn through the flux peaks at 5, 8 and 25 μm to represent the intrinsic energy distribution of the emitting source, the ratio $\tau_{18 \mu\text{m}}/\tau_{10 \mu\text{m}} \approx 0.35$ can be derived. The calculations of extinction cross sections for lunar silicates¹¹ yield the range 0.35–0.55 for the extinction ratio, which is in good agreement with the estimates discussed. We conclude, therefore, that the present observations of the position of the 18 μm absorption, and its strength relative to the 10- μm absorption, provide strong evidence to support suggestions that the absorbing agent is silicate dust.

The infrared flux received at the Earth from the AFCRL source at wavelengths between 2 and 33 μm is $3.3 \times 10^{-14} \text{ W cm}^{-2}$, approximately 20% of that energy falls within the 20–33- μm band. If the source is located at a minimum distance of 2 kpc (ref 5), as suggested by the molecular line emission at radio wavelengths, then the bolometric luminosity of the object exceeds $4.0 \times 10^4 L_{\odot}$. Similarly, the flux measured for OH 26.5+0.6 between 5 and 33 μm is $2.1 \times 10^{-14} \text{ W cm}^{-2}$. The distance to that source is unknown, however, assuming a nominal value of 500 pc (the distance to the Orion Nebula) a luminosity greater than $1.6 \times 10^3 L_{\odot}$ is obtained. For comparison, the total luminosity of the Orion point source is estimated to be $1.5 \times 10^3 L_{\odot}$ (ref 12).

By considering the observed infrared flux and distance of the Orion source, Becklin *et al.*¹² have concluded that BN cannot be simply a normal, luminous star hidden behind a dense interstellar dust cloud. The strong infrared signals and spectral similarity to BN of the two objects studied here imply a similar conclusion for AFCRL809–2992 and OH 26.5+0.6. Observations at higher resolution from 1 to 33 μm would undoubtedly be of importance in clarifying the relationship of these sources to objects such as BN and IRS5/W3, both of which are likely to be protostars still enshrouded by remnant dust shells.

We thank Dr G. Herbig for calling our attention to OH 26.5+0.6 and for providing a finding chart for this object. We also thank Dr D. Morrison for making available several band-pass filters.

Recent increase in Jupiter's decimetric radio emission

DURING an observational programme in support of a study of the linear polarisation properties of Jupiter's decimetric radio emission, it was noted that the planet's total intensity had increased between late summer 1973 and July 1974. The increase is small ($\sim 5\%$) but it seems to be a significant change in the trend of the past decade, during which time Jupiter's decimetric emission has decreased by 20–30% (refs 1–3) with respect to the flux densities observed before 1967.

The measurements were made at Goldstone, California, with the NASA 64-m parabolic antenna operating at 13.1 cm wavelength (2,295 MHz). Jupiter was observed on four nights between July 16 and September 11, 1973, and again on four nights between July 3 and August 17, 1974. The receiving system consisted of a rotatable waveguide polariser, a low-noise travelling-wave maser, and a noise-adding radiometer⁴ that provided stabilisation against short term gain variations. The linear polarisation parameters were determined from consecutive off-on-off measurements of Jupiter made with the polariser set to four different position-angle values at intervals of 45° . Antenna pointing errors were measured and corrected at regular intervals and the system gain was calibrated throughout each night by observing at least three of the radio sources 3C17, 3C48, 3C138, 3C286 and NGC7027. The flux densities of the calibration sources were subsequently determined relative to the radio galaxy Virgo A which has a flux density⁵ of 140.3 Jy at 2,295 MHz.

Jupiter's total intensity was computed for each set of four off-on-off measurements. The data are plotted as a function of the longitude of the central meridian (System III 1957.0) in Fig. 1. Both data sets exhibit the familiar periodic intensity variation with longitude (the beaming curve) but the 1974 data points are consistently above the corresponding 1973 values. The offset is several times greater

Fig. 1 The flux density of Jupiter at 13.1 cm is plotted as a function of System III (1957.0) longitude. O, data taken in 1973; ●, data taken in 1974.

than the uncertainty in the measurement caused by calibration discrepancies or by the effects of background radio sources near Jupiter's position in the sky. So I attribute the difference in flux density to an increase in Jupiter's decimetric radio emission.

It would be incorrect to measure the increase in the decimetric emission simply by determining the offset of one complete beaming curve with respect to the other because the shape of the observed curves varies as a function of D_E , the Jovicentric declination of the Earth⁵. But the strengths of the intensity peaks, which occur twice each rotation when the line of sight from Earth lies in Jupiter's magnetic equatorial plane, are expected to be independent of D_E . The flux densities near these two peaks were determined by fitting second order polynomials to the data with longitudes within $\pm 30^\circ$ of the peaks. The maximum flux densities in 1973 are 5.98 Jy and 5.99 Jy for the first and second peaks shown in Fig. 1. The corresponding values for 1974 are 6.35 Jy and 6.34 Jy. The average increase is 0.36 ± 0.06 Jy, the quoted uncertainty is chiefly the result of uncertainty in the relative calibration of the system from 1973 to 1974.

Fig. 2 Jupiter's peak flux density, normalised to a distance of 4.04 AU, is plotted against the date of the measurement. ●, Measurements at 11.1 cm (refs 7-9), 12.6 cm (ref. 1) and 13.1 cm (ref. 6), ○, a collection of measurements at 21 cm as assembled and published by Berge (ref. 3).

In Fig. 2 the average peak flux densities measured at wavelengths of 21 cm and 11-13 cm are plotted as a function of the epoch of each observation. The error bars, which range between 2 and 5%, are estimates of the relative standard errors. The flux density in both wavelength intervals seems to have decreased monotonically until mid-1972. The two 13-cm measurements reported here are the first to show a significant reversal of this downward trend and they demonstrate that Jupiter's decimetric flux density is variable with time scales as short as one or two years.

It is generally believed that the variations are related to changes in the properties of the Jovian Van Allen radiation belts, but specific causes of the variability have not been determined. Attempts to identify periodic variations that might be related to the 11-yr cycle of solar activity or the 12-yr period of the Jovian year have been unsuccessful¹⁻³. Reports of pronounced intensity variations occurring within weeks or months have been published. The most recent of these reports⁷ described variations as great as 30% occurring within a few days in 1968. In contrast, several high precision measurements made with the CSIRO 64-m antenna indicated that the Jovian flux at 11 cm and 21 cm was constant during the period 1963-67 (refs 8-10), and observations at 13 cm showed no variations larger than 2% during a 6-month interval in 1971 (ref. 1).

Variations in the intensity of Jupiter's radio emission is relevant to the analysis of particle and field data returned from spacecraft such as Pioneer 10 and 11. If the intensity variations are caused by physical changes within the Jovian radiation belts, the environment measured by Pioneer 11 will probably be different from that measured by Pioneer 10.

I thank the staff of the Mars Tracking Station at Goldstone for support and Dr S. Gulkis for discussions. Research was supported by NASA.

Shape of Mars

THE geometrical ellipticity of Mars differs considerably from the dynamical ellipticity obtained from the precession of the orbits of the satellites. Study¹ of the Martian centre of mass lead Schubert and Lingenfelter to comment that the location of the Hellas basin near the direction of the thinnest crust, as implied by the offset, might suggest that an impact produced the asymmetric crustal distribution. If such an impact did occur then it is likely to have also affected the shape of Mars. An order of magnitude estimate can therefore be made, from the shape of Mars, of the required size and velocity of the impacting body.

I take the value for the geometrical ellipticity e_s to be 0.0089 ± 0.0015 (ref. 2). For the dynamical ellipticity e , which is related to the second harmonic of the planets gravitational field, I take the value 0.005238 ± 0.00009 (ref. 3). Assume now that the rotation of Mars was greater at some past epoch for which the whole planet was in hydrostatic equilibrium. For such a case the ellipticity e_h can be defined as the fractional excess of the equatorial radius over the polar radius. The Darwin-Radau formula gives

$$e_h = \delta \left[\frac{2}{5} + \frac{5}{2} \left(1 - \frac{3}{2} \frac{C}{Ma^2} \right) \right] \quad (1)$$

where δ is the ratio of the centrifugal to the gravitational acceleration at the equator, C is the moment of inertia about the axis of rotation, M is the mass and a is the mean radius of Mars. I now assume that as a first approximation the ratio C/Ma^2 and the ratio a^2/M may be treated as remaining constant. Then

$$e_h = k_1 \delta = k_2 \Omega^2 \quad (2)$$

where k_1 , k_2 are constants of proportionality and Ω is the angular rotation of Mars. The assumption of total hydrostatic equilibrium gives the relationship

$$e = e_s = e_h \quad (3)$$

Let Ω_1 be the angular rotation of Mars before impact and Ω_2 its present angular rotation, for simplicity consider the axis of

rotation as unchanged I now assume that most of the planet is in hydrostatic equilibrium but that the surface has approximately the old ellipticity. Thus to obtain the value of Ω_1 which will make $e_h = 0.0089$, $\Omega_1 \approx 1.3\Omega_2$ (from equation (2))

To obtain some idea of the size and velocity which an impacting body may have to have in order to achieve this reduction in the angular velocity I consider a simple two dimensional situation where a body of mass m impacts with a velocity v tangentially to the surface of Mars and along its equator. I assume that the direction of impact is such as to reduce the rotation of Mars.

In an impact of this size dispersion of material would be expected to result and in a more exact treatment one would have to integrate the angular momentum about the axis of rotation of Mars for a distribution of secondary impacting bodies as well as for the primary object. Instead I assume a non-elastic rigid body impact which makes our treatment an approximate one. If the moment of inertia of Mars (about its axis of rotation) is $0.376Ma^2$ then from conservation of angular momentum

$$\begin{aligned}mv &\approx 0.376Ma(\Omega_1 - \Omega_2) \\ &\approx 0.1Ma\Omega_2 \\ v &\approx 20(M/m)\end{aligned}\quad (1)$$

since $a\Omega_2 \approx 200 \text{ m s}^{-1}$

The orbits of the asteroids are very varied, some have eccentricities of 0.8 or greater. Some asteroids have orbits which take them past the orbit of Jupiter. I now select an orbit which will give a large impacting speed and which is compatible with existing asteroid orbits to see whether this will give a reasonable mass for the impacting body. The orbit chosen is one which has an ellipticity of 0.8 and which comes close to the orbit of Jupiter. For simplicity take the orbit of Mars as a circle with unit radius. Take the elliptical orbit to be $r_{\max} = 3$ and $r_{\min} = \frac{1}{3}$ where r_{\max} and r_{\min} are the aphelion and perihelion distances. This gives a value of 0.8 for the ellipticity e , and r_{\max} is just less than the mean radial distance of Jupiter.

If I now take the Sun as origin I have for the equations of the orbits of Mars and of the impacting body

$$x^2 + y^2 = 1, \quad (x - c)^2 + y^2 / (1 - e^2) = a^2$$

where $a = 5/3$, $e = 4/5$ and $c = ae = 4/3$. For such an orbit (on calculations made using standard two-dimensional orbit theory) the speed of the impacting body at the moment of impact is $\sim 30 \text{ km s}^{-1}$ at an angle of $\sim 19^\circ$ to the major axis of the elliptical orbit. The speed of Mars is $\sim 24 \text{ km s}^{-1}$ at an angle of $\sim 150^\circ$ to the major axis of the elliptical orbit. So the impact speed relative to Mars is $\sim 32 \text{ km s}^{-1}$. This value could be increased slightly if the acceleration due to gravitational attraction was to be taken into account. Substituting this value for v in equation (1) gives as the required mass of the impacting body the value $m \approx 0.7 \times 10^{-3}M$. If the impact is assumed to be tangential at latitude 45° (approximately that of the Hellas basin) then $m \approx 10^{-3}M$ but if it is at an angle of 45° to the vertical then $m \approx 1.4 \times 10^{-3}M$. These values for m are about the same as the mass of the largest asteroid, assuming that the densities of Mars and of the asteroid are the same.

These calculations were made on the assumption that the difference between the geometrical and dynamical ellipticities is due to collision only. If other factors such as convection⁴ play a role the required size of the asteroid and the value of the orbital eccentricity of the impacting body may even be smaller.

I thank Professor S. K. Runcorn for encouragement and Dr D. J. Tritton for discussions.

CO₂ and HCN in sunspots

THE triatomic molecules CO₂ and HCN have now been reported to be present in cool stars^{1,2}, and H₂O had already been detected in the sunspot spectrum³⁻⁷. Dissociation equilibrium calculations for three recent sunspot models⁸⁻¹⁰ show that the molecules CO₂ and HCN are fairly abundant in sunspots. The results for the Zwaan model have already been published¹¹, we further find that the abundances of CO₂ and HCN are comparable for all three models. We have therefore calculated equivalent widths of selected lines of these molecules to ascertain if they might show up in the infrared region of the sunspot spectrum. The strongest fundamental bands of HCN and CO₂ and a weaker band of CO₂ were included in our calculations. The selected J values correspond closely to the expected maximum Local Thermodynamic Equilibrium (LTE) population under sunspot conditions.

The sunspot model selected for the equivalent width calculations is that of Stellmacher and Wiehr¹⁰. The procedure for calculating the equivalent widths has been outlined earlier¹². Two R (56) lines of CO₂ at wavenumbers $3,478.93 \text{ cm}^{-1}$ and $2,384.49 \text{ cm}^{-1}$, belonging respectively to the bands (10^01-00^00) and (00^01-00^00) of the $\Sigma-\Sigma$ transitions, were selected. The equivalent width of the former line at the centre of the disk turned out to be 0.032 mÅ suggesting an absence of the (10^01-00^00) band in the sunspot spectrum. Details of the centre-to-limb variation of equivalent width for the (00^01-00^00) line are given in Table 1.

Table 1 Equivalent width of (00^01-00^00) line

$\cos\theta$	1	0.7	0.5	0.3
Equivalent width (mÅ)	6.6	7.7	7.8	11.3

We are not aware of any observations of the (00^01-00^00) band of CO₂ in the $4.3 \mu\text{m}$ region of the sunspot spectrum and therefore a verification of these predictions with observations has yet to be done.

The R (25) line of HCN at $3,380.84 \text{ cm}^{-1}$, belonging to the band (00^01-00^00) of the $\Sigma-\Sigma$ type transition, in the Stellmacher-Wiehr¹⁰ sunspot model has an equivalent width of 0.072 mÅ at the centre of the disk. The fact that the other fundamental bands at 712 cm^{-1} and $2,089 \text{ cm}^{-1}$ have lesser integrated intensities¹³ leads us to suggest that the HCN fundamental bands may not show up in the infrared region of the sunspot spectrum.

Re-interpretation of Devensian Till stratigraphy of eastern England

THE current reconstruction of the Devensian Till stratigraphy of Holderness¹ invokes three units—the Drab, Purple and Hesse Tills—with the Hesse overlapping both lower tills so as to be the only one present in the westernmost part of the area, on the Yorkshire Wolds. Because of the characteristic reddish brown colours (usually 5YR4/4 of the Munsell Soil Colour Charts, 1954) of the uppermost tills throughout eastern England, the upper till in Lincolnshire and the Hunstanton Till of north Norfolk are equated usually with the Hesse Till¹⁻⁵, although Straw⁶ correlated his two Marsh Tills in Lincolnshire with the Drab and Purple Tills of Holderness, and Bisat⁷ equated the Hesse Till of the Yorkshire Wolds with his Middle Drab division.

The results of a mineralogical study on these tills⁸ have shed new light on these stratigraphic correlations. In Yorkshire, the Drab and Purple Tills are found to be essentially uniform in both texture and mineralogy, but distinct from one another, whereas the Hesse Till undergoes a transition in these properties between south-eastern Holderness and the Wolds. Maps (Fig 1a) may be drawn for various textural and mineralogical parameters, on the basis of which three zones can be distinguished (Fig 1b). Zone C covers western and northern parts of Holderness and the Yorkshire Wolds. No mineralogical or textural distinctions could be drawn between Straw's⁶ Upper and Lower Marsh Tills, and both these and the Hunstanton Till resemble closely the Hesse Till of Zone C in Holderness. This till is also texturally and mineralogically similar to the Drab Till, on which it can be seen to lie in deep sections. The only significant differ-

ences are the colours of the two tills, and the almost complete absence of siderite and pyrite from the coarse silt (20–53 μm) and fine sand (53–250 μm) fractions of the Hesse Till. The Hesse Till of Zones A and B likewise resembles the Purple Till in all but these respects. The use of selected mineral ratios (Fig 2) brings out most clearly the relationships between the various tills.

The coarse silt mineralogy of the Hesse Till of Zone C resembles that of loessial material that overlies the chalk on the Yorkshire and Lincolnshire Wolds and is also incorporated in a chalky head deposit beneath the Hesse Till⁹. Incorporation of loess in the till of western Holderness and the Wolds could thus be invoked to account for the change in composition of the Hesse Till. A large admixture of silt would however, be necessary but the Hesse Till of Zone C contains less silt than that of Zones A and B. Also, there are parallel changes in the fine sand mineralogy that could not be explained in this way, as loess contains very little fine sand.

The variability of the Hesse Till across Holderness may be related to the direction of ice movement, as the isopleths (Fig 1a) are approximately parallel to Devensian ice fronts postulated by several authors¹⁰. Similar variations occur in Wisconsinan tills in Ohio and Pennsylvania and are ascribed to progressive incorporation of underlying bedrock of a mechanical and mineralogical composition different from that of the original till material¹¹. There, however, the changes were greatest in the lowest till, whereas in Holderness it is the uppermost till that is most variable. Thus, the 'contamination hypothesis' only seems tenable if the Hesse Till was the product of a separate ice advance. Catt and Penny¹ could find no evidence to support that

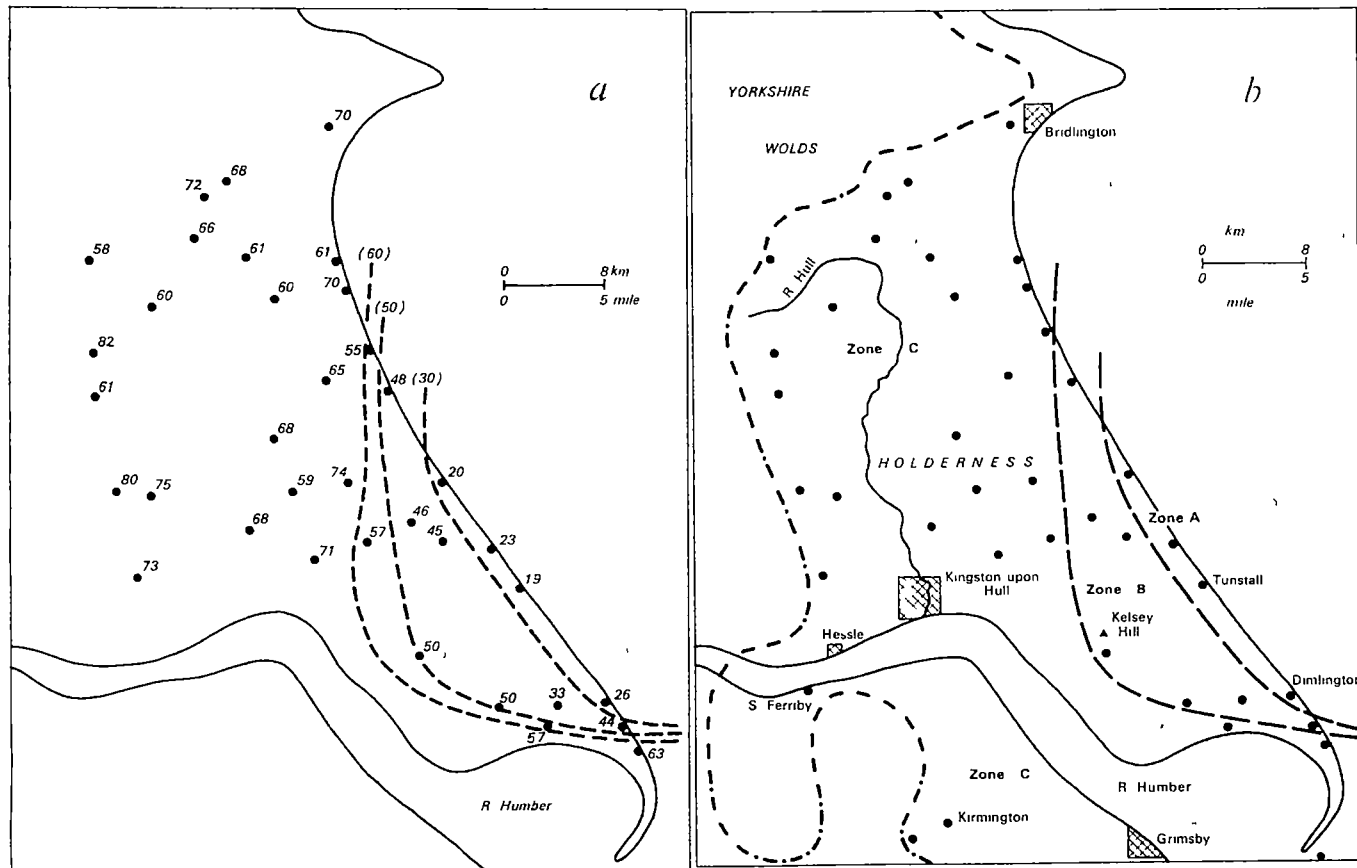

Fig 1 a, Mineralogical variability of the Hesse Till, 53–250 μm fraction (amphibole/(amphibole+pyroxene) $\times 100$), b, zonation of the Hesse Till in Holderness. ●, sampling sites, ---, western limit of Devensian tills

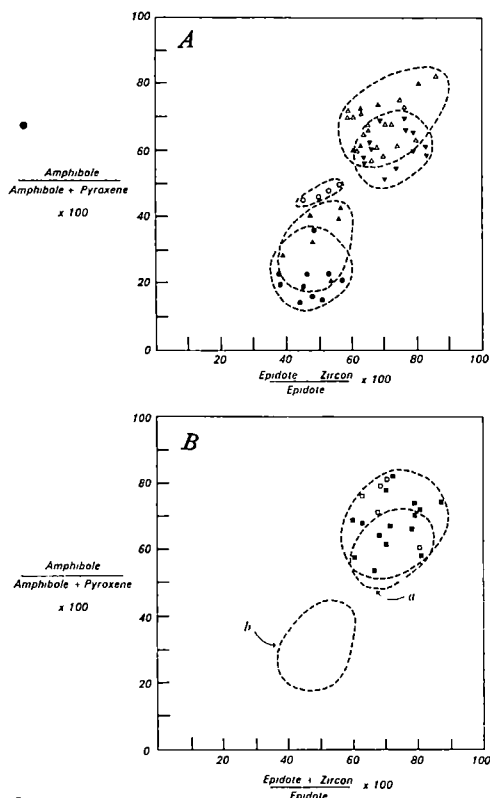

Fig. 2 Relationships between tills shown by mineral ratios
 A ●, Hessle Till, Zone A, ○, Hessle Till, Zone B, △, Hessle Till, Zone C, ▲, Purple Till, ▼, Drab Till B ■, Marsh Till, □, Hunstanton Till, a, Drab Till, b, Purple Till

suggestion, and regarded the entire Drab–Purple–Hessle sequence as the product of a single, composite Devensian ice sheet

Most of the variation in the Hessle Till seems to be related to the extent of the Purple Till, which is seen only in the cliffs of south-eastern Holderness and probably thins out westwards from the coast, as it is absent in the Hull Valley. The Hessle Till of Zone A is always underlain by Purple Till, and is mineralogically and texturally similar to it, whereas that of Zone C overlies Drab Till or Chalk, and is mineralogically and texturally similar to the Drab Till. The Hessle Till of Zone B occupies an intermediate position,

geographically, mineralogically and texturally, and may coincide with the feather edge of the Purple Till sheet

The exact junction between the Hessle Till and the underlying Drab Till is difficult to place, because the colour change often extends vertically downwards along fissures in the underlying grey (Drab) till, giving rise to reddish brown partings within it. Colour boundaries such as that indicate oxidative weathering, and siderite and pyrite, which are common in the Drab and Purple tills, but virtually absent in the Hessle, Marsh and Hunstanton tills, are both oxidised easily to hydrated ferric oxides, which would give the oxidised till a reddish brown colour. The grey Lower Marsh Till at South Ferriby (SE 996223) in Lincolnshire contains both siderite and pyrite, whereas the red till above it, which resembles the Hessle Till, lacks both minerals but is otherwise texturally and mineralogically identical to the grey till. Samples collected at metre intervals through the Hessle Till into the Purple Till at Dimlington (TA 398207) also proved to be mineralogically similar except for siderite and pyrite, both of which were present in samples close to and below the colour change taken as the boundary between the two tills. Further samples across the boundary between Purple and Drab tills at Dimlington High Land (TA 393215) and Aldbrough (TA 259395) showed that a mineralogical gradation occurs over a few metres close to this junction.

That leads to the conclusion that the Hessle Till, as currently defined, is in reality a composite unit. The reddish brown till of Zone C is the weathered upper part or feather edge of the Drab Till, and that of Zone B is probably the weathered remains of the thin westward extension of the Purple Till. That of Zone A is the weathered upper layer of the Purple Till. The name 'Hessle Till' is thus misleading stratigraphically, at the type locality it is, under the new interpretation, weathered Drab Till, whereas in south-eastern Holderness it is weathered Purple Till. Therefore, I propose that usage of the term be discontinued.

Straw⁶ subdivided the Marsh Tills of Lincolnshire into Upper and Lower units on the basis of their position either side of a 're-advance limit' of the last glaciation, which he recognised geomorphologically. I could detect no lithological differences between the two divisions, both tills were similar to the 'Hessle Till' of Zone C in Yorkshire. As this is now recognised to be weathered Drab Till, it seems reasonable to suggest that the Marsh Tills are also Drab or weathered Drab. A similar argument applies to the Hunstanton Till, which seems to be the oxidised, southernmost extension of the Drab Till. No till resembling either the

Fig. 3 East-west section across Holderness

Purple or the 'Hessle' of Zone A occurs in Lincolnshire or northern Norfolk

Many workers^{1,4-6,10} have cited the fresh, relatively undissected glacial morphology of Holderness, eastern Lincolnshire, and the coastal strip of northern Norfolk, in arguing for a Devensian age for the tills. This suggests the present distribution of the Drab and Purple Tills is depositional, and not primarily a result of subsequent erosion. The stratigraphic relationship of the Devensian Tills of eastern England is therefore one of offlap (Fig. 3) and not of overlap¹

Copper in surface waters south of New Zealand

THE sampling of the transition metals, including copper, in the ocean has so far produced unsatisfactory results. Reported measurements show quite a large scatter within a given suite of data and significant differences between investigators¹⁻³. Published profiles in general look quite unlike any of the 'accepted' distributions for other dissolved species outlined later nor are there any close similarities between the transition elements themselves. Either they have a unique geochemistry or the data are to some degree invalid. For copper, contamination during sampling has been suggested⁴ as one source of error, and we

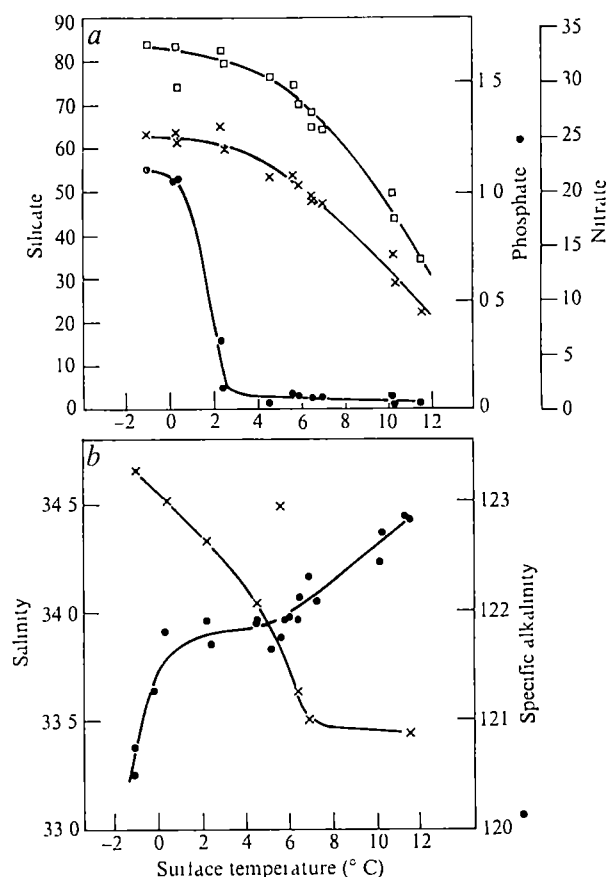

Fig. 1 a, Plots of surface values for phosphate, nitrate and silicate for all stations on GEOSECS Leg G against surface temperature. Units are $\mu\text{mol kg}^{-1}$. □, Phosphate, ×, nitrate, ●, silicate. b, Plots of specific alkalinity and salinity against surface temperature. For specific alkalinity (alkalinity/chlorinity) the unit is $\mu\text{eq per g chloride}$. ×, specific alkalinity, ●, salinity.

have tried to overcome this by sampling surface waters in regions of marked horizontal gradients in chemical properties.

Present understanding of the controls on the distribution of dissolved species in the ocean has been derived largely from inferences based on the form of the distributions themselves. Five types are presently recognised:

- (1) constant relative composition (Na, K, Mg, Cl, SO_4^{2-}) as a result of very low reactivity in the ocean environment,
- (2) surface depletion and deep water enrichment (P, N, C, Sr,

* Where the surface sample was collected more than 2 h before or after the shallow hydro cast, nutrients were also determined on the trace element water sample on the ship. The values are given below the station values.

- IO_3^- , Si, Ca, alkalinity, Ba, ^{226}Ra)^{5,6} caused by incorporation in the biogeochemical cycle (dissolved oxygen is a special 'inverse' case involved in the same cycle),
- (3) mid-depth and near-bottom depletion (^{210}Pb , ^{210}Po) caused by adsorption on suspended particles,
 - (4) pronounced mid-depth maximum (^3He) caused by injection at spreading ridge crests,
 - (5) near-bottom enrichment (^{222}Rn , ^{226}Ra , ^{228}Ra) caused by diffusion of radiogenic isotopes out of sediments

To date no categorisation has been made for any of the transition metals. Patterson⁴ has suggested that in spite of increasingly stringent precautions taken by trace element geochemists, a major unsolved problem is contamination during sampling. This problem can be most easily circumvented by restricting sampling to surface waters, however, the major criterion for validity of data is that it be oceanographically consistent. To apply this constraint requires sampling in regions of marked horizontal gradients in chemical properties. Such an opportunity arose on Leg G of the Pacific GEOSECS expedition, which made two sections south of New Zealand across the Circumpolar Current to $\sim 75^\circ\text{S}$. In this region major upwelling of deep water takes place, intensifying southwards. Plots of cruise data against surface temperature (Fig. 1) or latitude show

systematic increases for phosphate, nitrate and specific alkalinity and a step-like distribution for silicate.

Samples were collected on station from the bow of the ship. The sampler was a 4-l polyethylene jerry jug which had been leached with 0.1 N hydrochloric acid for 24 h, rinsed four times with very pure distilled water, and stored in a polyethylene bag. The jug was supported in a harness of polypropylene line. A metal weight encased in plastic was suspended about 6 m below this with similar line. First, the capped jug was lowered into the water and the exterior rinsed. It was then retrieved, the cap removed, resubmerged, and allowed to fill. The jug filled at a depth of at least 3 m. On recovery the jug was capped and within 5 min acidified with about 20 ml of 6 N hydrochloric acid which had been redistilled from a Vycor still. The bottles were stored in sealed polybags until analysis 2 months later.

Copper was preconcentrated from the samples by coprecipitation with cobalt pyrrolidine dithiocarbamate. The precipitate was redissolved in a small volume of methylethyl ketone with 5% 0.1 N HNO_3 . Copper was then determined by flame atomic absorption; the estimated precision of the analysis is $\pm 0.15 \text{ nmol kg}^{-1}$ and the blank is $0.45 \text{ nmol kg}^{-1}$.

The results of the analysis are given in Table 1 together with the relevant hydrographic and station data. The copper concentrations are all near the low end of the range of recently reported values^{1,2} ($1\text{--}32 \text{ nmol kg}^{-1}$) and exhibit variations of almost a factor of three that are correlated with surface temperature. In Fig. 2 the data are plotted against nitrate. This is the most precisely determined tracer of upwelling, the analytical precision being about 0.6% (for phosphate 0.7%). Also shown are similar plots for phosphate, silicate, salinity and specific alkalinity (A_{sp}). It is apparent from this and from Fig. 1 that the distribution of silica is quite distinct and that the copper-nitrate correlation resembles closely that for phosphate and alkalinity. The inverse relation for salinity reflects the precipitation patterns in the region: the existence of the Antarctic Circumpolar Front, at $\approx 4^\circ\text{C}$ precludes a simple mixing relationship.

The linear copper-nitrate trend has a least-squares standard error of 0.3 nmol kg^{-1} and the line passes through the origin ($-0.07 \text{ nmol kg}^{-1}$ at zero nitrate). The correlation coefficient is 0.88 and the molar ratio Cu/N is 1.09×10^{-4} giving a 'Redfield ratio' Cu/P of 1.7×10^{-3} . The recently reported average in plankton ash⁷ is 6.6×10^{-3} . Although the covariance of copper with the nutrients phosphate and nitrate is plausible, given the biochemical importance of copper⁸, it is not uniquely established from these data.

The scatter in the alkalinity data makes it difficult to relate to the other nutrients: a covariance of copper and alkalinity would, however, require that biogenic carbonates contain approximately 60 p.p.m. Cu. Arrhenius⁹ reported 25 p.p.m. in foraminiferal ash with 15 p.p.m. being associated with the carbonate fraction. Aragonitic corals generally show values less than 10 p.p.m. (ref. 10). *Acantharia radiolaria* which precipitate shells of celestite (SrSO_4) have been reported as containing 750 p.p.m. Cu (ref. 9). Accepting the general correlation of strontium with phosphate in the water column the average Sr/P ratio of 0.67 would require 840 p.p.m. Cu in the strontium carrier phase. Extrapolation of these hypothetical copper-carbonate and copper-strontium relationships gives zero copper at a specific alkalinity value of 119 and a strontium concentration of $87 \text{ } \mu\text{mol kg}^{-1}$, that is, copper is exhausted long before the major carrier components: this is highly unusual behaviour for a solid solution.

In conclusion, it is definitely established that relative to lower latitudes, copper is enriched in the surface waters of the Antarctic upwelling areas, and, by extension, in the deep waters of the ocean. If the correlation with nitrate is valid as described here, then copper can be classified as a limiting nutrient. The levels in the surface water in low and mid-latitudes should be very close to zero (less than 0.1 nmol kg^{-1}) and the maximum values in the deep Pacific should not exceed 5 nmol kg^{-1} .

We thank the officers, crew and scientific party of RV Melville for their help and the members of the Science Advisory

Drag reduction by collapsed and extended polyelectrolytes

I REPORT experiments on drag reduction by saline solutions of a partially hydrolysed polyacrylamide (PAMH) showing the effect of macromolecule conformation. The extreme collapsed and extended PAMH conformations also simulate the deportment of linear random-coiling macromolecules in solution, and of high aspect ratio fibres in suspension, and they indicate a possible relationship between the mechanisms of drag reduction produced by these additives.

A commercial PAMH polymer, B1110 (Betz Laboratories), $M = 15 \times 10^6$ was used. This has an intrinsic viscosity, $[\eta] = (2,300, 2,550, 6,000, 16,000, 52,000) \text{ cm}^3 \text{ g}^{-1}$ in (1.0, 0.1, 0.01, 0.001, 0.0) M NaCl solutions respectively. The radius of gyration of B1110 in 1.0 M NaCl was 315 nm, in dilute distilled water solution B1110 is expected to be greatly extended, to an end-to-end distance of the order of its contour length, $\sim 70 \mu\text{m}$.

Friction results for collapsed and extended conformations are shown in Fig 1, using Prandtl-Karman coordinates with abscissae based on solvent viscosity. The behaviour of solutions of collapsed polyelectrolyte, Fig 1a, is identical with that established¹ for random-coiling macromolecules. Solutions of 1 and 10 parts per million (by weight) of B1110 follow curve (1) for $Re_s f^{1/2} < 200$, transit to curve (2), exhibit an onset of drag reduction at $Re_s f^{1/2*} \sim 400$ and follow straight lines for $Re_s f^{1/2} > Re_s f^{1/2*}$ with slopes exceeding that appropriate for a Newtonian fluid. B1110, 100 p.p.m., follows curve (1), $Re_s f^{1/2} < 250$, and curve (3), $Re_s f^{1/2} > 350$. Among solutions of extended polyelectrolyte, Fig 1b, 10 p.p.m. B1110 in distilled water follows curve (1) for $50 < Re_s f^{1/2} < 200$, for $200 < Re_s f^{1/2} < 400$ it seems to transit to the maximum drag reduction asymptote, but at $Re_s f^{1/2} \sim 400$ it breaks away into the polymeric regime, and then for $500 < Re_s f^{1/2} < 2,000$ it describes a straight line, $(S_p, I_p) = (5.0, 3.1)$, roughly parallel to but lying above the Prandtl-Karman law. Qualitatively similar behaviour occurs at 3 and 30 p.p.m. Solutions of 100 p.p.m. show marked shear thinning in laminar flow (power law index 0.60 ± 0.01 for $40 < Re_s < 4,000$) and for $Re_s f^{1/2} > 400$ seem to transit to the maximum drag reduction asymptote, the data points lying nearly parallel to curve (3) for $700 < Re_s f^{1/2} < 1,500$ with horizontal separation corresponding to $\eta_{rel} = 1.5$. So the

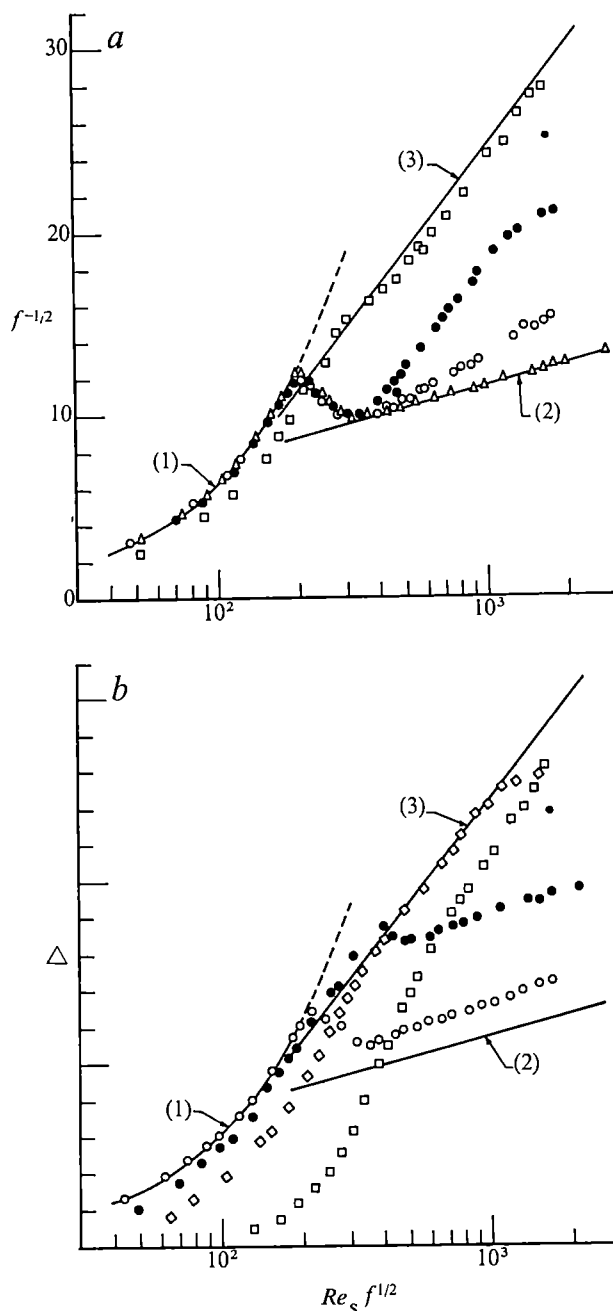

Fig. 1 Drag reduction by solution of a, collapsed polyelectrolyte, b, extended polyelectrolyte. Pipe internal diameter 0.945 cm, length 189 cm, polymer B1110, temperature $21 \pm 2^\circ \text{C}$. The solid lines represent (1) Poiseuille's law (denoted L), (2) the Prandtl-Karman law (N), and (3) the maximum drag reduction asymptote¹ (M). In the region between (2) and (3), called (4) the polymeric regime (P), polymer solutions can be seen to follow approximately linear relationships defined by their slope and intercept (S_p, I_p) . a Δ , Distilled water (DW), \circ 10 p.p.m. in 0.1 M NaCl, \bullet 100 p.p.m. in 1.0 M NaCl, \square 100.0 p.p.m. in 0.1 M NaCl. b \circ 3.0 p.p.m., \bullet 10.0 p.p.m., \star 30.0 p.p.m., \square 100.0 p.p.m. All in DW.

maximum drag reduction possible with extended polyelectrolytes seems to be limited by the usual asymptote, curve (3), with increasing $Re_s f^{1/2}$, the typical solution follows a path sequence LMP which contains a characteristic 'retro-onset' point $Re_s f^{1/2*}$ at which the polymeric regime segment departs from curve (3). Both slope and intercept of the polymeric regime segment increase with increasing polyelectrolyte concentration but all slopes are characteristically close to Newtonian. The LMP trajectory contrasts strikingly with the LNP trajectory typical of random-coiling polymer solutions.

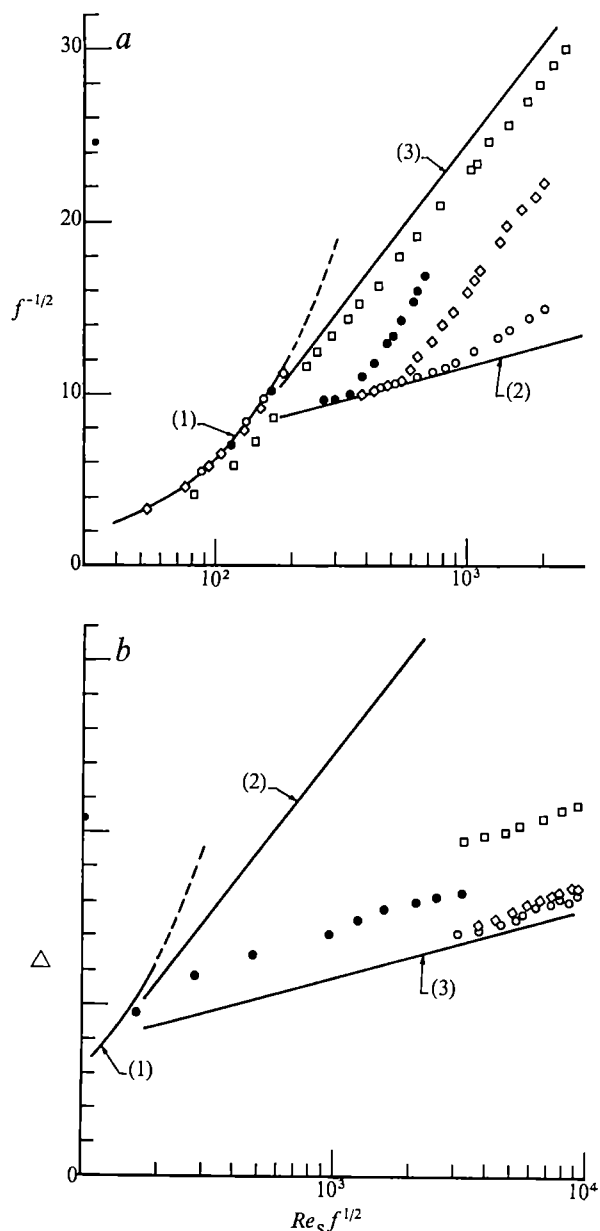

Fig. 2 Drag reduction by *a*, random-coiling polymer solutions, *b*, fibre suspensions⁴⁻⁶ *a* ○, 10.0 p.p.m., W205, ★, 100.0 p.p.m., W205, ●, 10.0 p.p.m., FRA, □, 110.0 p.p.m., FRA. All DW solutions, all pipe 0.945 cm internal diameter except □, 1 d 0.846 cm. *b* ○, 10⁴ p.p.m., nylon, ●, milling yellow crystals, ★, 800.0 p.p.m. asbestos, □, 2,500.0 p.p.m. asbestos ○, 1 d 4.98 cm, ●, 1 d 7.79 cm, ★, and □, 1 d 5.08 cm

Study of 10 p.p.m. B1110 in 1.0, 0.01, 0.001 and 0.0 M NaCl revealed a continuous variation in flow behaviour between the extremes shown in Fig. 1. In terms of drag reduction, measured by fractional flow enhancement $S_F = (-1 + (f_p^{-1/2}/f_s^{-1/2}) Re_s f^{1/2})$, relative efficiencies were $S_F(1.0 \text{ M}) < S_F(0.01 \text{ M}) < S_F(0.001 \text{ M}) > S_F(0.0 \text{ M})$, so a partially extended conformation was 'optimal' for $300 < Re_s f^{1/2} < 2,000$. Relative efficiencies of different conformations were, however, decidedly flow dependent, in Fig. 1 the 1.0 M and 0.0 M NaCl solution trajectories intersect making $S_F(1.0 \text{ M})$ less than, equal to and greater than $S_F(0.0 \text{ M})$ for $Re_s f^{1/2}$ less than, equal to and greater than 1,000 respectively. Possibly, therefore, the apparent conflict between the data of Parker² and of Hand³ may not be serious.

The present results can be related to drag reduction by random-coiling polymer solutions and by fibre suspensions using Fig. 2. Part *a* shows flow data for two polyethyleneoxide (PEO) polymers, FRA, $M = 8 \times 10^6$ and W205, $M = 1.3 \times 10^6$. PEO macromolecules possess a skeletal structure similar to

that of PAMH, and the FRA chosen has roughly the same number of skeletal links, $N \sim 0.5 \times 10^6$, as B1110. There is close correspondence between the 10 and 100 p.p.m. B1110 data in Fig. 1*a* and the 10 and 110 p.p.m. FRA data in Fig. 2*a*. Figure 2*b* illustrates drag reduction by fibre suspensions using data reported for suspensions of a nylon fibre⁴, milling yellow crystals⁵ and two chrysotile asbestos fibres⁶. The fibre suspensions all produce approximately straight lines which lie in the region between curves (2) and (3), possess slopes only slightly greater than the Prandtl-Karman, 4.0, and yield essentially constant drag reduction, independent of $Re_s f^{1/2}$. The milling yellow suspension yields $(S_p, I_p) = (4.5, 0.8)$ and $S_F \sim 0.23$ (constant) for $300 < Re_s f^{1/2} < 3,000$. The gross flow behaviour (Fig. 2*b*) which seems to be characteristic of fibre suspensions, is analogous to that exhibited by extended polyelectrolyte solutions (Fig. 1*b*) in the polymeric regime.

Results obtained with collapsed and extended polyelectrolyte possibly represent two extremes of drag reduction behaviour, one (designated Type A) which is characteristic of flexible, random-coiling, deformable additives and the other, (Type B) which is characteristic of relatively rigid, elongated, undeformable additives. Idealised, a family of Type A solutions yield polymeric regime segments fanning outwards from a common onset point on the Prandtl-Karman line with slopes increasing with increasing additive concentration and drag reduction increasing with increasing $Re_s f^{1/2}$. A family of Type B solutions yield polymeric regime segments coming off the maximum drag reduction asymptote at characteristic retro-onset points and lying roughly parallel to but displaced upwards from the Prandtl-Karman line with drag reduction essentially independent of $Re_s f^{1/2}$ but increasing with increasing additive concentration.

Novel reactions of hydrocarbon complexes of metal-substituted sheet silicates: thermal dimerisation of *trans*-stilbene

TRANSITION metal, ion-exchanged montmorillonites form complexes^{1,2}, often of an interlamellar kind (intercalates), with a range of aromatic molecules, including benzene, toluene and the xylenes, anisole, and other species such as *trans*-stilbene and indene³⁻⁵. The aromatic molecules can form two main types of complex with the interlayer transition-metal ions, for example Cu(II). In the first type there is thought to be an edge- π -bonded copper arene moiety, similar to the bonding situation which exists in $C_6H_6CuAlCl_4$ (ref. 6), and in the second instance it is considered to be a type of bond which causes associated distortion of the aromatic ring and some localisation of the circumferential double bonds¹. Although detailed crystallographic analyses of the organic intercalates of sheet silicates has only recently commenced (ref. 7, and J. M. Adams *et al.*, unpublished) and in spite of the paucity of information relating to the precise nature of the bonding of organic entities to encaged metal ions, it is clear²⁻⁴ that these organic complexes display a rich range of unusual reactions, some new examples of which we report here.

Complexes of benzene, toluene, the xylenes and *trans*-stilbene were formed with dehydrated Cu(II)-exchanged montmorillonite by exposing the latter to the vapour of each

respective aromatic material. Excess *trans*-stilbene was removed by washing with chloroform, and surplus solvent was removed by suction. On heating the complexes *in situ* in an AEI MS30 mass spectrometer, in high vacua, between 50 and 250° C, high molecular weight products appeared.

With the benzene complex of Cu(II) montmorillonite, which is known to involve the second type of linkage between the metal and the aromatic ring, only a negligible proportion of material possessing a molecular weight approximately two or three times that of benzene was produced, whereas with the toluene complex, which has the first type of linkage, appreciable quantities of molecules of mass number 272 and 182 were formed (Table 1). These mass numbers correspond to three toluene units less four hydrogen atoms and to two toluenes less two hydrogens, respectively. Complexes of all three xylenes, which have similar copper-arene linkages to the toluene complex, behaved very similarly and yielded mass numbers of 314 and 210, again signifying the loss of hydrogens when three and two units, respectively, of xylene condense. Blank mass-spectrometric experiments carried out with sodium-ion-exchanged montmorillonite revealed that, essentially, no hydrocarbon of higher molecular weight was formed when traces of physically adsorbed alkyl benzene were heated in the absence of the transition-metal ion.

With *trans*-stilbene, the results were strikingly different in that significant quantities of material possessing a mass number of 360, which corresponds to the dimer, were obtained. (Some ions with *m/e* equal to 370–450 were observed in low abundance, so some trimer or even higher order species must have been formed, although the molecular ion(s) corresponding to such species were not observed.)

Although much remains to be learned about the mechanisms of these thermally induced reactions the obvious major difference in the nature of the products obtained suggests that different reaction pathways are followed depending on whether the organic molecules contain aromatic rings or aromatic rings together with ethylenic double bonds. The implication, which needs to be tested, is that the central olefinic double bond in *trans*-stilbene is bonded to the Cu ion and that, as a result of the proximity and the electronic perturbation of these olefinic double bonds of the two (or more) *trans*-stilbene molecules, dimerisation is facilitated. Though it is unnecessary to postulate that the dimerisation is concerted, it is of interest to note that the thermal production of tetraphenyl-cyclobutane from *trans*-stilbene monomers is, by orbital symmetry, forbidden and that the photochemical dimerisation, though allowed, is not easily achieved either in the solid state^{8,9} or when weakly physically adsorbed¹⁰.

Systematic position of *Plesiadapis*

THE systematic position of the Palaeocene mammal *Plesiadapis* has been a subject of discussion for almost a century.* This is not surprising considering the meagre evidence on which it was first associated with lemuroid primates. A review of the evidence now available indicates that the affinities of *Plesiadapis* and its relatives are with early tarsier-like primates, and not with archaic lemurs.

Gervais¹ described the genus *Plesiadapis* after he² and Delfortrie³ had recognised *Adapis* as a primate related to living lemurs. Gervais' species *Plesiadapis tricuspidens* was originally based on two specimens collected by Lemoine from the Palaeocene of France—a mandible fragment and an isolated incisor—neither of which show any significant resemblance to *Adapis*. The relationship between *Plesiadapis* and *Adapis* advocated by Gervais was apparently based on several Eocene specimens first described by Lemoine as *Plesiadapis*⁴, but subsequently transferred to the new, genus *Protoadapis*⁵ (which is closely related to *Adapis*).

Once given a name compounded from *Adapis*, no matter how poorly justified that actually was, it is natural that *Plesiadapis* was subsequently compared most closely with lemur-like primates. Simpson⁶ emphasised the detailed resemblance of the molar pattern of *Plesiadapis* to that of the early adapid *Pelycodus*, and classified the Plesiadapidae as a family within the Lemuroidea⁷. The presence of a postprotocingulum ('*Nannopithecus*-fold') on the upper molars of *Plesiadapis*, *Pelycodus*, and early Eocene tarsiid primates is an important derived characteristic shared by early primates⁸ but, considering the important differences now known in the anterior dentition of species of *Plesiadapis* and *Pelycodus*, it appears that Simpson overestimated the significance of their molar resemblances. *Plesiadapis* also differs significantly in middle ear structure from early lemuroid primates.

In a group of mammals with a reasonably good fossil record, a biostratigraphic approach to phylogeny⁹ offers the best evidence for working out the true relationships between species. Virtually all specimens assigned to the family Plesiadapidae have been studied again in a carefully documented biostratigraphic context¹⁰. Five plesiadapid lineages are known, at least two of which were common to both Europe and North America. Particularly interesting here is the major lineage leading from *Prionothodectes matthewi* of the middle Palaeocene (Torrejonian) to *Platychoerops richardsonii* of the early Eocene (Cuisian).

Plesiadapis tricuspidens is a late member of this central lineage. As the earliest plesiadapid and the common ancestor of all the later species known, *Pronothodectes* is the primitive form

Fig. 1 Comparison of the lower dentition of representative Eocene Tarsiiformes (*Nannopithecus* (a), *Omomys* (b)) with that of middle Paleocene Plesiadapiformes (*Palenochtha* (c), *Plesiolestes* (d), and the primitive plesiadapid *Pronothodectes* (e)). Note enlargement of the central incisor distinguishing these forms from lemuriform and anthropoid primates. c, Lower canine. All figures in lateral view and brought to same size for comparison, bar represents 1 cm. Specimens are a, Halle IL-8, Geiseltalmuseum in Halle; b, AMNH 12600, YPM 13219, 16287, American Museum of Natural History, New York; c, PU 14786, 19461; d, PU 14149, 17427, Princeton University Museum, New Jersey; e, USNM 9332, National Museum of Natural History, Washington, AMNH 35462.

which should be compared with members of other families in determining the relationships of Plesiadapidae.

Pronothodectes matthewi is similar in dental conformation to early species of Carpolestidae, Paromomyidae, and Microsyopidae (Paromomyidae is limited here to forms having tricuspid plesiadapid- or carpolestid-like upper incisors, including *Paromomys*, *Phenacolemur*, and possibly *Saxonella*; whereas the Microsyopidae, including *Plesiolestes*¹¹, *Palaeochthon*, *Palenochtha*, *Berruvius*, *Navajovius*, have simpler bicuspid upper incisors¹⁰.) All have a basic dental formula of

$$\begin{array}{cccc} 2 & 1 & 3 & 3 \\ 2 & 1 & 3 & 3 \end{array}$$

and all have enlarged, procumbent, pointed, lower central incisors. Early Tarsiidae and Omomyidae have the same basic dental formula and very similar lower incisors, with one possible exception: some specimens of *Teilhardina* apparently retained four premolars, although descriptions of the dental morphology of this genus are conflicting and deserve additional study. The lower dental formula of microchoerines is sometimes cited as 1.1.4.3 (ref. 12), but interstitial wear on the medial side of the enlarged anterior tooth shows it to be the central incisor, and the 'alveolus' in front of this tooth is an anterior mental foramen¹⁰.

Figure 1 shows that the mandibular and dental conformation of Palaeocene primates of the infraorder Plesiadapiformes is very much like that of Eocene Tarsiiformes (Plesiadapiformes Simons, 1972¹³ includes the same four families as Paromomyiformes Szalay, 1973¹⁴ and the former name is used here). The morphology of the anterior teeth differs fundamentally from that seen in the earliest lemuroid primate *Pelycodus* and its descendants. The lower central incisor (I_1) of *Pelycodus* is slightly smaller than I_2 and both are considerably smaller than the canine. Furthermore, the incisors of adapids differ in being vertically implanted and in having spatulate rather than pointed crowns.

The auditory bulla and middle ear are exceptionally well preserved in a skull of *Plesiadapis tricuspidens* recently collected by M. Pellouin of Reims from the Palaeocene locality of Berru in France. The auditory bulla in this skull was completely ossified, with no trace of a separate entotympanic element (though an entotympanic centre may have been present during ossification). Russell¹⁵ has described the extended external auditory meatus and fusion of the tympanic annulus into the lateral wall of the auditory bulla in another skull of *Plesiadapis tricuspidens*; the skull illustrated in Fig. 2 shows these characters even more clearly. An extended external auditory meatus and a tympanic annulus fused into the wall of the bulla characterise all Tarsiiformes but not primates of the infraorder Lemuriformes or

Fig. 2 Right auditory bulla of Pellouin skull of *Plesiadapis tricuspidens* in ventral view (stereophotograph). Note *Necrolemur*-like¹² struts anchoring the tympanic annulus to the lateral wall of the bulla. Fragments were removed from the ventral wall of the bulla to facilitate cleaning. A.t., Annulus tympanicus; C.c., Canalis caroticus; M.a.e., Meatus acusticus externus. This skull of *Plesiadapis* includes an almost complete maxillary dentition, on which its identification is based. Bar represents 1 cm.

primitive Anthropeoidea. The ear region of the skull of *Plesiadapis* (and *Phenacolemur*¹⁶) thus furnishes additional evidence linking plesiadapiform primates to Eocene *Necrolemur*, Oligocene *Rooneyia* and living *Tarsius*, and to the origin of Tarsiiformes.

In both dental conformation and middle ear morphology, generally recognised as the two character complexes of greatest systematic importance among early primates, plesiadapiformes are very similar to early Tarsiiformes and differ greatly from early Lemuriformes. Evidence is presented elsewhere suggesting that Anthropeoidea are derived from lemuriform rather than tarsiiform ancestors¹⁷. Thus there seems, from the fossil evidence, to be a basic dichotomy within the primates separating the infraorders Plesiadapiformes and Tarsiiformes on one hand from the infraorders Lemuriformes and Anthropeoidea on the other^{10,18}. The earliest lemuroid primates appear abruptly in the fossil record, suggesting that they migrated to Europe and North America at the beginning of the Eocene (as did the earliest rodents and several other important groups). *Purgatorius*, from the Early Palaeocene¹⁹, is the only form known which could possibly be the last common ancestor of all later primates.

I thank Drs E. L. Simons, F. A. Simons, D. R. Pilbeam, J. A. W. Kirsch and J. H. Ostrom of Yale University for numerous discussions and for their comments on the manuscript. I also thank Drs W. A. Clemens (Berkeley), R. J. Emry (Washington), G. L. Jepsen (Princeton), M. C. McKenna (New York), P. Bultynck (Brussels), H. W. Matthes (Halle), D. E. Russell, (Paris) and M. Pellouin (Reims) for access to specimens described here. Financial support from a Shadle Fellowship of the American Society of Mammalogists is acknowledged.

Collective orientation in night-flying insects

SEVERAL investigations have been made using microwave radar techniques to study individual insects in free flight^{1–5}. One of the most surprising claims to result from these studies is that insects flying at night sometimes adopt a common orientation, usually downwind^{1,2,4}. This would imply a remarkable ability to determine wind direction when flying in conditions of severely limited visibility¹. We report here an instance of collective insect orientation in nocturnal flight, although in this case, the direction of flight was against the wind.

Our observations were made at Kara in the Niger flood plain in Mali during October, 1973, using radar apparatus

Fig. 1 Typical detection envelopes for two targets of radar cross section (σ) 1 cm² and 4 cm². Targets of these sizes will not be detected outside their respective envelopes. The volume swept out by the envelopes on rotation of the aerial about a vertical axis, and therefore the volumes sampled per revolution for the two sizes of targets, are substantially different. The angular scale in this diagram has been multiplied by 10 to make the effect clear.

modified for entomological observations⁵. The aerial of this radar projects a 'conical' pulsed, microwave beam the axis of which can be set at selected angles of elevation. Rotation of the aerial about a vertical axis causes targets at the appropriate elevations round the radar to be illuminated briefly once per revolution. The resulting radar echoes, if large enough, are registered as 'dots' on a conventional display revolving in synchrony with the aerial. Small targets may be detected at short range and close to the beam axis; larger targets are detectable at greater ranges and further from the axis of the beam. Figure 1 shows typical detection envelopes for two sizes of target. A given airborne volume density of large targets will thus produce more display 'dots' per revolution than the same density of smaller targets.

Measurements made on captive insects indicate that they generally form substantially larger radar targets when the electric vector in the radar wave has a large component parallel to the insect's major body axis^{6,7}. In the case of a radar transmitting horizontally polarised radiation, this means that flying insects will generally present larger 'echoing areas' when flying broadside on to the radar than when end on². A uniform distribution of insects flying with a degree of common orientation in the vicinity of the radar would thus be expected to produce a non-uniform radar display, more 'dots' being seen in the directions from which insects presented predominantly side-on aspects to the radar than in other directions. A pronounced example of this effect is shown in Fig. 2. The distribution of echoes shown in this photograph implies that the insect targets in the vicinity of the radar were predominantly aligned with the 35–215° axis. This 'polarisation' of the echo distribution does not indicate in itself which way along this axis the insects were heading.

Evidence for direction and confirmation of the collective orientation suggested by the polarised display was given by time-lapse photographs of the radar screen. Individual insect echoes were seen to move in the direction of 35° at a ground speed of $\sim 3 \text{ ms}^{-1}$ while the radar echo produced by a freely flying balloon (circled), at the same altitude ($\sim 900 \text{ m}$) and carrying strips of aluminium foil, was displaced towards 215° at $\sim 2 \text{ ms}^{-1}$. The insect heading in this case was clearly against the wind. The aerial density of insects varied from $\sim 50 \text{ per } 10^7 \text{ m}^3$ at 900 m altitude to 20 per 10^7 m^3 at 100 m. The sky was clear with a 7/8 Moon at a bearing of 250°.

The 'polarisation' effect was observed on several nights, being present for 2 or 3% of the observational period (ten nights). The opportunity to provide simultaneous observations

Fig. 2 Photograph of radar screen (1946h, November 3, 1973 at Kara, Mali). Elevation angle 46° , distance between range rings 500 yd. True north is at 0° on the display scale. The echo produced by a freely flying balloon is circled.

of balloon displacement and 'polarisation' did not, unfortunately, recur on these occasions, so that no general implication about heading with respect to wind direction could be inferred. What the observations do show is that some insects regularly demonstrate an ability to adopt a common orientation when flying at night at altitudes of several hundred metres and when separated from each other by distances of the order of 50 m or more.

Information about the identity of insect targets may be gained by measuring the frequency of the modulation produced in their radar echoes by their wing flapping action⁷. Figure 3 shows the distribution of wing-beat frequencies deduced from radar measurements of a sample of the insects responsible for the echoes shown in Fig. 2. Comparison of this histogram with the wing-beat frequencies of other insects found in the

Fig. 3 Histogram showing the distribution of fundamental frequency components detected in radar signatures recorded from targets contributing to the polarised display in Fig. 2. Numbers on the vertical axis indicate the number of signatures containing fundamental frequency components per unit interval of frequency.

area suggests that the echoes may have been caused by grasshoppers, possibly *Trilophidia*, *Oedaleus* and *Locusta*.

Micromanipulation of stomatal guard cells

THE opening and closing of stomatal pores is controlled by deformations of the guard cells resulting from changes in the pressure relationships between epidermal and guard cells. Under natural conditions such changes are, in turn, controlled by changes in the osmotic concentrations of cell saps or by changes in cell water content, although they could also be controlled by changes in cell wall properties. We have measured the pressures required to bring about or maintain stomatal openings by applying pressures directly within subsidiary cells and guard cells of *Tradescantia virginiana* and *Vicia faba* leaves.

Fig. 1 Pressures applied in subsidiary cells of *Tradescantia virginiana* leaves which caused stomatal closure at various degrees of opening. Each point is the mean of at least 10 measurements with the exception of the values at 3.7 and 25.9 μm where four measurements were made. The pressure values quoted are the total pressures prevailing in the guard cells and not the pressure differentials between epidermal and guard cells. The intercept with the Y axis represents the pressure required to force liquid through the opening of the microneedle. In this species pressures obtained with epidermal strips were of the same magnitude as those with intact leaves. When one of a pair of guard cells was punctured before the application of pressure, the same pressures were required to cause a given degree of opening as with both guard cells intact; this implies that in this species guard cells do not assist each other during movements. Pressures applied in subsidiary cells to close initially open stomata were of the same magnitude as those applied within guard cells to re-open initially almost closed stomata. Until now we have been unable to open completely closed stomata. This observation tends to support Stålfelt's concept of 'Spannungsphase' during which either greater pressures than 10 bar are required before guard cells are deformed; or we must postulate that changes in cell wall properties take place during this phase. The shape of the curve suggests that until an opening of about 10 μm has been reached the deformations of the walls in this species do not involve any substantial stretching of the guard cells. With openings above this size, guard cell walls begin to expand against gradually increasing resistances.

The technique (details will be published elsewhere) consisted of inserting water-filled needles (diameter $<1\ \mu\text{m}$) into the cells and exerting positive or negative pressures using a special syringe attached to the needle. At the same time a transducer was used to measure the magnitude of the pressures, while changes in stomatal pore widths were measured using a microscope with an eyepiece graticule.

Figure 1 shows a summary of the results obtained with *Tradescantia virginiana*. Except during the 'Spannungsphase', operative pressures in the stomatal apparatus were lower than would be expected from some plasmolytically determined osmotic potentials of guard cell saps^{1,2}. Such discrepancies could result from inherent weaknesses in the plasmolytic method. Alternatively, the assumption that guard cells of open stomata (even during steady state openings) are at maximum turgor (in other words, that osmotic potential differences determined plasmolytically cannot be equated to pressure potential differences of guard cells) could be wrong. A mechanism preventing the attainment of full turgor by guard cells can be postulated by reference to the evidence for substantial water vapour loss to the leaf air space from epidermal cells³ and to the outside from guard cells⁴. These possibilities seem to be supported by the comparatively gentle curvature of the line in Fig. 1, suggesting that it is unlikely that these cells were at full turgor. The possibility that guard cell wall properties are unusual and changeable could also be postulated in view of the evidence for ionic migrations between epidermal and guard cells, or between cell walls, the protoplast and vacuoles⁵⁻⁷. These postulates are currently being tested.

We wish to thank the S. R. C. for financial support which made this work possible.

The corneal cones of *Limulus* as optimised light concentrators

In their external shape and optical properties, the crystalline cones of the ommatidia in the compound eye of *Limulus polyphemus* strikingly resemble ideal light collectors. Such devices were developed¹ in a totally different context: for the purpose of optimising the collection of the extremely faint radiation produced in a transparent medium by faster-than-light charged particles (Cherenkov light). Ideal light collectors are ogival-shaped light guides designed to maximise the concentration of diffuse light within a specified angular acceptance. These light guides are optically homogeneous and derive their characteristic properties from the specific shape of the exterior surface which is made specularly reflecting.

Figure 1 illustrates the performance of an ideal light collector. All light rays incident upon the entrance pupil S_1 at an angle $\theta < \theta_{\max}$ are channelled through the exit pupil S_2 after undergoing perhaps one or more reflections. The rays emerge with a large angular spread, approaching 90° to the cone axis. For the

Fig. 1 Profile of ideal light concentrator for maximum angle of acceptance $\theta_{\max} = 19^\circ$. All light rays incident upon the entrance pupil within a cone of aperture θ_{\max} are collected and conveyed to the exit pupil. On the right branch of the profile, the shape of a crystalline cone of *Limulus* is also shown.

ideal collector, the concentration factor $x = S_1/S_2$ is related to the angular acceptance θ_{\max} by

$$x = 1/\sin^2 \theta_{\max} \quad (1)$$

This performance is characteristic of an optical system with $f/\text{number} = 1/2$, the theoretically lower limit to the relative aperture imposed by geometrical optics. A complementary property of such systems is to exclude any stray light incident at angles greater than θ_{\max} .

The qualitative similarity between the profile shape of an ideal light concentrator (Fig. 1) and that of the crystalline cones of *Limulus* became apparent from a micrograph^{2,3} of the anatomy of the compound eye of this Xiphosurid. A quantitative match of the profile shape of several crystalline cones with theoretical shapes corresponding to various acceptance angles θ_{\max} showed a very good fit for $\theta_{\max} = 19^\circ$. This is in fact the value of the parameter θ_{\max} for the profile shown in Fig. 1, where the comparison with the shape of a typical crystalline cone of *Limulus* is indicated. Cone shapes corresponding to smaller acceptance angles occur near the periphery of the eye.

The simplest optical mechanism by which the *Limulus* cones could function as ideal light concentrators involves total internal reflection of the incident light at the interface between the crystalline cones and the surrounding media. For an optically uniform cone of refractive index $n = 1.54$ (refs 4 and 5) in optical contact with tissue fluid of $n = 1.34$ (ref. 5), the collection of light would be highly efficient, since only a small fraction of light rays would impinge on the internal cone wall at angles in excess of the critical angle (nearly 60°) and leak out. A similar analogy between the ellipsoid portion of retinal cone cells and ideal light collectors has already been noted⁶.

Since the crystalline cones, protruding inward as part of the corneal cuticle, are embedded for about two-thirds of their length in a transparent matrix whose optical properties have never been critically analysed, it was necessary to test the assumptions of our model. The lateral eyes of adult female specimens of *Limulus* were excised and the cornea cleaned of the rhabdomes and pigmented tissue. Throughout all observations, the specimen samples were kept immersed in the original tissue fluid. A portion of the interior visual surface thus prepared is shown in Fig. 2a, where the resemblance of the cone

Fig. 2 *a*, Interior surface of the central area of the cornea in the lateral (compound) eye of *Limulus polyphemus*. Fresh specimen, immersed in tissue fluid ($\times 33$). *b*, Interior of the visual surface, as in *a*, when illuminated by a diffuse source from the exterior side of the cornea. The light entering the crystalline cones is channelled to their tips ($\times 33$). *c*, Interference contrast micrograph of the *Limulus* cornea. Fresh section ($10\ \mu\text{m}$ thick) normal to the exterior surface near the periphery of the eye. The section is immersed in tissue fluid. A bright fringe outlines a crystalline cone, whose refractive index is higher than the intracrystalline fill ($\times 55$). *d*, Interference contrast micrograph, as in *c*, of a section parallel to the corneal surface. Bright circular fringes define the cross sections of the crystalline cones ($\times 55$). *e*, Enlarged view of fresh section of the corneal matrix filling the space between crystalline cones. The cross section of the pore canals, filled by tissue fluid is made visible by interference contrast ($\times 133$). *f*, As in *e*, in a longitudinal view. The darker area on the left is part of a crystalline cone ($\times 133$). *g*, Images of a grid (mesh opening $3\ \text{mm}$) placed in front of the visual surface at a distance of $2.6\ \text{cm}$. The images are focused at the tips of the crystalline cones, when the latter are immersed in water. The field of view subtended by each cone belonging to the central region of the eye, is approximately 20° ($\times 48$). *h*, Image obtained at the tip of a lucite macroscopic replica of a *Limulus* cone, having the theoretical profile shape of ideal light concentrators. Lucite cone immersed in water ($\times 38$).

shapes with the profile of Fig. 1 can clearly be seen. The gross light-concentrating properties of the crystalline cones are illustrated in Fig. 2*b*. Even in the absence of pigment, they behave as light guides, concentrating the light incident on the external surface of the cornea on to the tips of the cones, where the rhabdomes are normally attached. Frozen sections ($\sim 10\ \mu\text{m}$ thick) were then observed with a Baker double focus interference microscope. The crystalline cones preserved their optical identity throughout the entire depth of the cuticle. Their shape is clearly outlined (Fig. 2*c* and *d*) by a bright fringe marking a decrease in refraction index from the interior of the cones to the embedding matrix. All corneal material consisted of cuticle laminations separated by layers of fluid, local variations in the average refractive index, such as that at the cone boundary, arising from variations in the spacing and thickness

of such laminations. The cone interior has a remarkably uniform refractive index, as previously shown⁴. Although the gross refractive properties of the intracrystalline fill can be described in terms of an average measured refractive index $n \sim 1.48$, closer inspection reveals a highly inhomogeneous structure for this tissue (Fig. 2*e* and *f*). It has a loose fabric, permeated by pore canals⁵ running normally to the cuticle laminations. Tissue fluid in the matrix of pore canals seems effectively to constitute a liquid sheath surrounding the highly refracting crystalline cones. The relevant refractive indices for total internal reflection are then those of the cone and tissue fluid respectively, as previously considered⁵.

The phenomenon known as 'pseudopupilla'⁷ is readily explained in our model. All light entering the ommatidium through a cone with angular acceptance θ_{max} is collected and does not re-emerge. In these conditions, the entrance pupil seems a velvety black: the ommatidium behaves as a light sink. Moreover, our simple model of a homogeneous, highly refracting crystalline cone is capable of accounting for the remarkable imaging ability of the crystalline cones observed by many investigators⁷. It is precisely this imaging property (Fig. 2*g*) which prompted earlier attempts to invoke complicated mechanisms for their optical function. A model of the crystalline cone consisting of a lucite light guide ($n=1.5$) with the ideal collector profile immersed in water ($n=1.33$) reproduces the images observed at the tip of an actual cuticular cone of *Limulus*.

Several assumptions have been made in our analysis. The laminated structure of the crystalline cones and the finite thickness of the optical discontinuity at the cone boundaries will make the light collector somewhat inefficient, particularly towards the cone tip. The extent of this light leakage can be appreciated from Fig. 2*b*. In *Limulus* the problem is overcome by encapsulating the distal part of the cone in a sleeve of cells bearing reflecting-pigment, the guanophores⁸.

We conclude that the ommatidia of *Limulus* provide a good example of an optimisation process in nature. Among the possible advantages to an organism that evolves ideal light collectors, the most important is probably the ability to see in dim light conditions.

We thank Drs J. Enoch and G. Bernard for helpful discussions; G. Bernard for samples; Dr W. A. Anderson for enabling us to make fresh frozen sections; and Dr H. H. Swift for the loan of a Baker interference microscope. This research was supported in part by the Alfred P. Sloan Foundation. The material in this paper was presented at the ARVO Spring Meeting in Sarasota, Florida.

Recovery of haemolytic plaque-forming cells after freeze drying

FREEZE drying is generally accepted as the most convenient and often the best method for the preservation of bacteria and viruses. With mammalian cells, the situation is different and

cells such as lymphocytes have to be stored in liquid nitrogen, a method that is cumbersome and inconvenient and which makes transport of such cells particularly difficult. Up to the present, there has to our knowledge been only a single report of successful recovery of function following rehydration of a freeze dried nucleated mammalian cell. This was by Meryman and Kafig in 1959¹ using spermatozoa, but neither they² nor other workers³ have been able to repeat this work. Freeze drying of non-nucleated mammalian cells, such as erythrocytes, has been more successful, however, and both Meryman⁴ and Greaves⁵ have reported the lyophilisation of small numbers of these cells.

The use of cryoprotectants such as dimethylsulphoxide (DMSO) or glycerol are commonplace in the cryopreservation of cells. These substances penetrate the cells and obviate freezing damage probably because of their ability to 'buffer' salt concentration by their colligative properties⁶. When freeze drying is carried out, these substances being non-volatile become concentrated at levels toxic to most cells²⁻⁶. The use of polyvinylpyrrolidone (PVP) in conjunction with foetal calf serum (FCS) has been investigated⁷. PVP does not penetrate the cell and following the previous work it seemed worthwhile to try to use it to protect cells against damage by freeze drying. Here we describe the successful recovery of a lymphocyte function following freeze drying of cells from a medium containing PVP and FCS. The function we chose to investigate is the formation of haemolytic antibody (IgM) as demonstrated by the production of plaques of haemolysis in thin layers of sheep red blood cells (SRBC) by spleen cells from mice previously sensitised with SRBC. This was chosen because of the high sensitivity and specificity of the test.

For each experiment, six female mice (Porton albino) were each injected intravenously with 5×10^8 SRBC. Four days later, the spleens were removed and homogenised by gentle sieving through a nylon sieve. The cells were washed with Medium 199 by centrifugation for 10 min at 190g and were resuspended in Medium 199. The total number of white cells was counted in the normal way in a haemocytometer and the cell density of the suspension adjusted to 5×10^6 ml⁻¹. The number of plaque forming cells (PFC) was estimated by the method of Cunningham and Szenberg⁸. Aliquots of the cell suspensions (5 ml) were distributed in centrifuge tubes, spun for 10 min at 190g and resuspended in one of two previously prepared cryoprotective media. The first was 10% (v/v) DMSO in Hanks solution, the second was 14% (w/v) dialysed PVP (average molecular weight 24,500; Koch-Light Laboratories Ltd., Colnbrook, UK) supplemented with 30% (v/v) FCS in Hanks solution⁷. In preliminary experiments with mouse spleen cells this medium was examined at pH 7.2 and 6.0 and the latter was found to be better for freeze drying. This may have been because the rise in the pH value due to loss of CO₂ from the serum⁹ was balanced by the lower initial pH. In the results presented the pH of the PVP/FCS medium was adjusted to 6.0 as a routine.

For freezing and drying, 10-ml vials (neutral necked vials, Specification no. 1 (M) 3479, Johnsen and Jorgensen Ltd, London) were used, freezing being carried out in 1-ml amounts and freeze drying in 0.1-ml amounts. The samples were cooled slowly (approximately 2° C min⁻¹) on the pre-cooled shelves (-40° C) of the EF6 freeze drier (Edwards High Vacuum Ltd)

Table 1 Recovery of total number of mouse spleen cells and plaque-forming cells after freezing and freeze drying in 10% DMSO

Cell suspensions	Total white cell recovery		PFCs

Freeze dried and rehydrated	2.1	42	130	11
	1.5	30	150	13
	2.3	46	170	15

Control suspension contained cells in Medium 199, the cell density being adjusted to 5×10^6 cells ml⁻¹, 5 ml being examined. The cell suspensions in the PVP/FCS medium were divided into three groups and treated as follows. First, cells from three 5 ml samples were centrifuged again and resuspended in Medium 199. This was devised as a control for the manipulation other than freezing and drying. Second, cell suspensions from three 5 ml samples were distributed in vials and frozen in 1 ml mounts; this was the control for freezing without drying. Third, suspensions from three 5 ml samples were dried in 0.1 ml amounts. After rehydration, pooling in 5 ml amounts and subsequent centrifugation, the pellets of these samples were resuspended in Medium 199. All the experimental groups were examined in triplicate.

* Each value is average of counts in two chambers.

down to -38° C and -40° C and then removed and thawed quickly in a water bath at 37° C (1-ml samples) or freeze dried (0.1-ml samples). For the latter, as soon as a vacuum of 0.07-0.09 torr had been obtained, the temperature of the shelves was raised slowly (2 h) to -20° C, and drying carried out at this temperature for 2 h. The vials were then cooled again to -40° C, dried for an additional 20 h and sealed under vacuum with rubber stoppers. This technique resulted in a residual moisture of 8-10% which was determined by a microdrying method¹⁰. To rehydrate the cells, 0.1 ml of cold Medium 199 was added on the surface of the freeze dried cake, the vials being kept at -40° C. After the medium had frozen the vials were removed from the cold shelves and stood at room temperature to allow the ice to melt. Thus the cake was rehydrated at the temperature of melting ice. The thawed and rehydrated samples were pooled in 5.0-ml amounts, centrifuged and resuspended in Medium 199. The total white cell counts and the number of PFCs were then determined.

Table 1 shows the results of tests when DMSO was used as a cryoprotectant. 78% of the total number of cells was recovered from the freezing and thawing process, while only 10% of the original PFC survived. When the cells were rehydrated following freeze drying, only 15% of the total cells were found and not a single PFC. These results are typical of our experience with the use of DMSO. It is a satisfactory cryoprotectant as far as freezing is concerned but it is toxic when used in a process involving freeze drying.

Table 2 shows the results obtained in an experiment in which PVP and FCS were used to protect the cells. In several experiments, we had found a substantial loss in the total cells and PFCs during the manipulations before either freezing or freeze drying. Such a loss is shown in Table 2. In spite of this, however, it is clear that 30-40% of the total cells have been recovered from the complete process, while 11-15% of the PFC have come through. If the loss of cells due to the manipulations is taken into account, the recovery of total cells from the freeze drying process becomes nearly 100% and the recovery of PFC nearly 30%. No change of total cell numbers or PFC was noticed after 7 d storage at 4° C.

Having thus established that cells dried in the presence of DMSO would not produce haemolytic plaques whereas those

freeze dried from PVP would, we decided to investigate various properties of the plaques. In particular, we wished to know whether the plaques were produced by antibody; whether antibody was secreted or diffusing; or whether antibody synthesis was involved.

The results shown in Table 3 pertain to the first two questions. The total abolition of plaques by azide, found on more than one occasion, shows that plaque formation is energy dependent and thus not the result of simple leakage of preformed material from damaged cells. That the plaques are formed by IgM antibody is shown by the facts that no plaques are formed in the absence of complement, that plaque formation is inhibited by dithiothreitol and that anti- μ -chain serum which is immunologically specific for the μ chain of mouse IgM molecules also blocks plaque formation. Thus, the results show that plaques are formed by IgM molecules secreted from cells by a process requiring energy and, as haemolysis occurs when sheep red blood cells are the target cell and not when chicken erythrocytes are used as a target, it is clear that the required specificity of the antibody exists and demonstrates that the plaques are due to specific IgM and are not an artefact.

Table 3 Haemolytic plaque formation by rehydrated freeze dried cells

Experiment	Total white cell count (ml ⁻¹ × 10 ⁶)		PFCs*					
	1	2	1	2	2a	2b	2c	2d
Control	5.0	4.8		1,100				
		4.7	435	965				
		5.1	1,035

	2.8	1.2	210	485				
	3.0	1.4	230	375				
Freeze dried and rehydrated tested as Exp. 1	1.4							
	1.1	—	0	—	—	—	—	—
	1.4							
Freeze dried and rehydrated	1.8	1.1	345	135				
	2.0	1.4	325	130	0	0	0	0
	1.7	1.0	380	100				

Experimental details are as given in Table 2. In experiment 1, 10⁻¹ M azide was added to one group of chambers. In experiment 2, the following variations were used: 2a, the chambers contained no complement; 2b, the chambers contained chicken red blood cells in place of sheep red blood cells normally employed; 2c, the chambers contained 1 drop of 1:2 dilution of rabbit anti-mouse μ -chain serum; 2d, the chambers contained 10⁻¹ M dithiothreitol.

* Each value is average of counts made in two chambers.

Further information on the level of cellular integrity was sought by the use of an inhibitor of protein synthesis, in this case puromycin. This antibiotic causes chain termination by forming a peptide bond with the nascent polypeptide forming on the ribosome¹¹. In a preliminary experiment, puromycin at 10⁻⁴ M inhibited PFCs by about 60%. A further experiment was set up, the results of which are shown in Table 4, from this it can be seen that puromycin at 10⁻² M failed to give complete inhibition of PFC in either the control or the prefrozen and manipulated samples, giving in fact a reduction to around 17% and 10% respectively (with 10⁻³ M puromycin, the figures were 70% and 60%). In the case of freeze dried and reconstituted cells, there was virtually no inhibition at 10⁻³ M but the 10⁻² M concentration gave a reduction to about 40%. These results would seem to indicate that there has been a selection of non-puromycin sensitive cells following freeze drying but that there is still a proportion of these cells in which some degree of protein synthesis, that is, production of nascent polypeptide chains, is occurring.

We have also considered the freeze drying aspects of this problem. The moisture levels reported here are high relative to the standards accepted in microbiology. It should be noted, however, that the 'microdrying' method for moisture determination used in the present study is based on the loss in weight of a

Table 4 Effect of puromycin on plaque formation by mouse spleen cells

Experiment	Total white cell count (ml ⁻¹ × 10 ⁶)	PFCs*		
		Normal	10 ⁻³ M puromycin	10 ⁻² M puromycin
Control	5.6	5,740	3,665	1,150
	6.3	6,135	4,335	1,020
	6.7	5,485	4,165	870

	4.7	1,685	1,295	565
	3.9	1,245	1,190	530

* Each value is average of two counts made in two chambers.

5–10 mg sample on drying in a vacuum at an elevated temperature (80–100° C) and is said to give considerably higher moisture contents than the so-called American standard method¹⁰. Further, we have demonstrated experimentally that even at moisture levels of 2.7% as determined by the Baker method¹⁰, PFC can still be found although at lower recovery rates, 25% of PFCs in control compared with 45% at 11% moisture. The inability of hitherto reported mammalian cells to withstand dehydration to a water content below about 25% (refs 12 and 13) renders our results even more encouraging.

We have also been able to show that freeze dried cells with a residual moisture content of around 5% can be stored for up to 3 weeks at room temperature and still retain their capacity to produce plaques.

The number or proportion of PFCs recovered following freeze drying is currently very variable and at present we have no satisfactory explanation of this fact. Analysis of results from six separate experiments and two storage experiments shows that the results were variable. Geometric means and standard deviations were calculated from log transformed data. The geometric means found (shown with their s. d.) varied from as few as 6.1^{+4.9} PFCs recovered from 197.9^{+27.6} PFCs to as many as 35.2^{+4.9} PFCs from 37.2^{+7.9} PFCs. Most results, however, are not as extreme as these and suggest that a mean recovery of 10–15% of the PFCs in the original spleen cell suspension is found after all manipulative and freeze drying losses. The loss due solely to freeze drying and rehydration is difficult to assess now. The puromycin experiments indicate that some selection of cell population occurs during these processes.

Our experiments suggest the inadequacy of the more commonly used intracellular cryoprotectant agents, such as glycerol and DMSO, for protecting cells against the effects of freeze drying. These agents concentrate within the cell during the sublimation of the water and reach levels that are toxic to the cells^{3,6}. With DMSO in our study, not a single PFC survived. It would seem, therefore, that only those mammalian cells which can survive freezing without glycerol or DMSO may be potential candidates for freeze drying. The extracellular protective medium used here has recently been developed by us⁷ and it has been shown to protect effectively human lymphocytes against freezing damage.

The haemolytic effects seen in our experiments are shown to be due to the active secretion of complement-fixing, antigen-specific IgM molecules. At least some cells seem to be involved in polypeptide synthesis on the ribosomes. Thus, a degree of functional integrity of the cell has been demonstrated and we believe therefore that the work we have described represents a novel and important step towards the recovery of fully functioning nucleated mammalian cells following freeze drying. It may be noted also that for the first time drying-rehydration injury has not been of a higher degree than freezing-thawing injury. So far even in the preservation of micro organisms, freeze drying has always been more deleterious than freezing¹⁴.

We are grateful to Mrs A. Bruton for technical assistance. Rabbit anti-mouse μ -chain serum was a gift from Dr. C. Desmayard.

Evidence against interconversion of microtubules and filaments

MICROTUBULES, hollow cylindrical structures of diameter ~ 250 Å and variable length, consisting of 13 protofilaments (diameter ± 40 Å), are now generally accepted as an essential constituent of most eukaryotic cells. They have been implicated in such diverse functions as: maintenance of cell shape, intracellular transport and organisation, movement (particularly slow morphogenetic movement) and control of cell surface topography (for review see ref. 1).

In general, cytoplasmic microtubules are intermingled with filaments (diameter ~ 100 Å), and it has been suggested that they are two components of one functional system. The (supposedly) rigid microtubules would then serve as rails along which organelles are transported through interconnecting filaments². Numerous observations both *in vivo* and in cell culture systems have shown that disruption of microtubules is followed by the appearance of large amounts of filaments often arranged in tightly packed bundles^{3–7}. This has usually been interpreted as an interconversion of microtubules into filaments (refs 3 and 8). Other authors, however, favour the idea that depolymerisation of microtubules would result in a redistribution of existing filaments from a dispersed status to an aggregated form⁹.

Unfortunately, the very nature of these structures does not make it feasible to perform accurate morphometric studies which could solve the problem. We have compared the effect of different antitubulins at different dose levels and with prolonged incubation times, in particular the vinca alkaloids, considered to be very useful in this context, since these drugs are able to precipitate microtubular protein as crystalline aggregates at higher dose levels. We have tested the following hypotheses: (1) If microtubules and filaments are composed of the same precursor protein then there should be an inverse relationship between filament whorls and 'microtubular' crystals in cells treated with vinca alkaloids. (2) If there is a redistribution (aggregation) of filaments after microtubular disruption then these filaments should be absent in the zones between the bundles. (3) If the occurrence of bundles is due

to enhanced synthesis of filaments then this should be largely inhibited by inhibition of protein synthesis.

Cells from a C3H mouse embryonal cell line (MO; ref. 10) show contact inhibition of both movement and division, and form transparent sheets of large polygonal cells at confluency. When these cells were treated with antitubulins* (colchicine, vinblastine and vincristine) they lost their characteristic stretched appearance and assumed a flattened round form. This coincided in time with the disappearance of microtubules at the ultrastructural level, and with a total loss of intracellular orientation and compartmentalisation. This was most obvious in the organisation of the Golgi field which has a perinuclear position around the centrioles in untreated cells and 'explodes' completely after microtubule dissolution, with individual Golgi organelles being distributed over the entire cytoplasm; and the centrioles often assume a peripheral position. Both subplasmalemmal microfilaments and 100 Å filaments were obviously unaffected. The foregoing took place within 10 to 80 min, depending on the dosage used ($100\text{--}0.04\text{ }\mu\text{g ml}^{-1}$). After 2 h a proliferation of smooth endoplasmic vesicles occurred, which later subsided, followed by a general hypertrophy of the rough endoplasmic reticulum and the appearance of annulated lamellae. Increased amounts of 100 Å filaments were observed after only 5 h, bundles and whorls of which continuously increased in size and number, and reached a maximum after 24–48 h (Fig. 1a). The zones between the bundles still contained individual filaments.

When cells were treated for prolonged periods (24–48 h) and subsequently replaced in normal growth medium they regained their normal stretched appearance within 24 h. At the ultrastructural level this coincided with the reappearance of microtubules, beginning after about 4 h, and consequent intracellular reorganisation. Within 24 h the centrioles reassumed their normal perinuclear location in the centre of the regrouped Golgi zone. Filament whorls diminished in size and number, however, at a very slow rate, large aggregates still being observed after 48 h. Both the rate of appearance of filament accumulation after treatment and the disappearance after discontinuation of treatment can hardly be explained by either interconversion of microtubules in filaments or a mere redistribution of pre-existing filaments.

We tried to check the most likely explanation: an enhanced synthesis of filaments after microtubule dissolution. Cells were pretreated with cycloheximide ($10\text{ }\mu\text{g ml}^{-1}$) followed by colchicine ($1\text{ }\mu\text{g ml}^{-1}$) after 16 h. In this situation (which produced a 95% inhibition of labelled leucine incorporation into acid precipitable material; M.D.B., unpublished), the cells reacted in the same way, except for the total lack of filament whorls even after 48 h of treatment (Fig. 1b). Individual filaments could, however, be observed throughout the cytoplasm. Additional evidence against interconversion of microtubules and filaments was obtained by treating the cells with vinca alkaloids. Both vinblastine and vincristine produced effects identical to those of colchicine, filament bundles occurring in the same amount at all doses tested ($10\text{--}0.1\text{ }\mu\text{g ml}^{-1}$). At doses above $1\text{ }\mu\text{g ml}^{-1}$, however, an additional feature appeared: the occurrence of large crystalline aggregates, with a tubular substructure, most prominent at $10\text{ }\mu\text{g ml}^{-1}$. These structures, known to be composed of tubulin^{8,11}, did not interfere in any way with the concomitant presence of filament whorls (Fig. 1c).

These results show that neither interconversion of microtubules in filaments nor redistribution of pre-existing filaments are sufficient explanations for the appearance of large filament aggregates in MO cells after microtubule dissolution. Moreover, it can hardly be attributed to a side-effect of the drug used, since it is produced by all known antitubulins regardless of their often totally different chemical nature. The most likely explanation is obviously an excessive synthesis of filamentous protein.

Although the function of these filaments has not yet been completely elucidated, they always occur in close connection

Fig. 1 *a*, Bundle of filaments (*f*) in the vicinity of the nucleus (*n*) in a MO cell treated for 24 h with colchicine ($1 \mu\text{g ml}^{-1}$) ($\times 26,000$). *b*, Perinuclear region in a MO cell treated for 24 h with cycloheximide ($10 \mu\text{g ml}^{-1}$) followed by colchicine ($1 \mu\text{g ml}^{-1}$) after 16 h. Filament bundles are completely absent although individual filaments are present. ($\times 22,000$). *c*, Perinuclear region in a MO cell treated for 24 h with vinblastine ($10 \mu\text{g ml}^{-1}$). Both filament bundles (*f*) and crystalline structures (*c*) are present. ($\times 11,000$). The cells were cultured in Eagle's minimum essential medium supplemented with 10% foetal bovine serum. For observation with the phase contrast microscope and subsequent fixation for electron microscopy the cells were cultured in Falcon plastic Petri dishes (6 cm ϕ). At the appropriate moment the medium was decanted and the cultures washed twice with saline at room temperature. The cells were fixed with 5% glutaraldehyde in 0.1 M sodium cacodylate at room temperature for 15 min and postfixed with a mixture of 4% glutaraldehyde and 1% osmium tetroxide at 0°C . After dehydration in a graded alcohol series the cells were embedded in epon. Under the phase contrast microscope individual cells were selected for further processing for electron microscopy. A minimum of 50 cells was examined per treatment group, each cell being sectioned in a semi-serial fashion from bottom to top, to exclude major sampling errors.

with microtubules in untreated cells. On the other hand, they frequently seem to make contact with organelles such as mitochondria and lysosomes^{12,13}. This has led to the supposition that filaments, together with microtubules, could be responsible for the intracellular directional movement of these organelles^{2,14,15}. A possible hypothesis is that the increased production of filaments after microtubule dissolution could be due to some feedback mechanism whereby the loss of one component of the system (microtubules) is, to some extent, overcome by the hypertrophy of the other component, which could presumably take over some of the lost functions.

Morphine antagonises action of prostaglandin in neuroblastoma and neuroblastoma \times glioma hybrid cells

WORK on cell lines derived from tumours of the nervous system has been carried out to establish models for neurones and glial cells. Clonal cell lines derived from mouse neuroblastoma C 1300 possess many properties characteristic of neurones¹⁻¹¹. While the neuroblastoma cells increase in their intracellular levels of adenosine 3',5'-cyclic monophosphate (cyclic AMP) in the presence of prostaglandin E_1 (PGE_1) (refs 12 and 13), acetylcholine¹⁴ and adenosine¹⁵, rat glioma cells¹⁶ do so when exposed to noradrenaline^{17,18} or PGE_1 (ref. 19).

Hybrids between mouse neuroblastoma and rat glioma cells display remarkable neuronal properties. In contrast to their parental lines, they contain choline acetyltransferase^{20,21}. They are rather large cells capable of extending long processes; they fire action potentials in response to depolarisation by electrical current or acetylcholine²¹, they contain clear and dense core vesicles²² and have dopamine- β -hydroxylase activity⁵; they increase their content of cyclic AMP in the presence of PGE_1 (ref. 19).

In the course of our studies on the action of PGE_1 on neuroblastoma cells and their hybrids, we investigated²³ the potency of substances, which had been reported^{24,25} to interfere with the influence of prostaglandins. Among these we examined morphine²⁶, as the opiate is known to inhibit the contractions of intestinal muscle^{25,27,28} evoked by PGE . Here we report that morphine antagonises the stimulatory action of PGE_1 on the level of cyclic AMP in neuroblastoma and neuroblastoma \times glioma hybrid cells. While this work was in progress²⁶, Collier and Roy reported that morphine inhibited the stimulation by PGE_1 of the formation of cyclic AMP in rat brain homogenates²⁹.

The neuroblastoma¹³ and neuroblastoma \times glioma hybrid¹⁹ lines which are most responsive to PGE_1 were cultured in plastic dishes 10 cm in diameter. For experimental incubation, the cells were kept for 10 min at 37°C , at varying concentrations of morphine in the absence or presence of $10 \mu\text{mol l}^{-1}$ PGE_1 as described previously²³. Morphine hydrochloride, dissolved in Dulbecco's modified Eagle's medium, was added (50 μl) to 5 ml

of incubation medium. After the incubation, medium and cells were separately assayed for cyclic AMP^{23,30}. The data are referred to cellular protein³⁰.

Curve *a* of Fig 1 demonstrates that morphine at concentrations between 0.1 and 100 $\mu\text{mol l}^{-1}$ inhibits the increase of cyclic AMP levels evoked by PGE₁. Up to 12% of the total cyclic AMP thus formed is found in the incubation media (Fig 1, curve *b*). Release of cyclic AMP into the surrounding media has been described previously^{23,31}. As the fraction of cyclic AMP released from the cells is always low in these conditions, however, the corresponding data are omitted from the subsequent figures. The inhibitory action of morphine decreases at concentrations above 0.1 mmol l^{-1} (Fig 1, curve *a*). We observed²³ a qualitatively similar phenomenon using another antagonist of PGE₁, 7-oxa-13-prostanoic acid²⁴. It remains to be established whether or not the two phases of Fig 1, curve *a* correspond to the sites of stereospecific and non-stereospecific opiate binding³². In cells not stimulated by PGE₁, no effect of morphine on the level of cyclic AMP is noticed (Fig 1, curve *c*). Again, only about 10% of the total cyclic AMP is found in the medium.

On exposure to PGE₁ the level of cyclic AMP reached in neuroblastoma \times glioma hybrids is considerably higher than in neuroblastoma line N4TG3. The cells are more sensitive to morphine than N4TG3 (Fig 2, curve *a*). The 50% inhibitory concentration (IC₅₀) is 5 $\mu\text{mol l}^{-1}$ for the hybrids compared with 400 $\mu\text{mol l}^{-1}$ for the neuroblastoma line. In three further series of experiments with N4TG3, however, the IC₅₀ was in the range of 5–20 $\mu\text{mol l}^{-1}$. The causes for this scattering of morphine-sensitivity values are under investigation. IC₅₀ values of 5 $\mu\text{mol l}^{-1}$ were also reported for the adenyl cyclase system in brain homogenates²⁹. In considering the cell culture system as models for nervous tissues in intact animals, it is important that it is also micromolar concentrations of morphine in brain which exert an antinociceptive effect (data recalculated from ref 33). Similar to the neuroblastoma line, the hybrids show no sensitivity to morphine in the absence of PGE₁ (Fig 2, curve *b*).

The morphine analogue naloxone is known to antagonise the action of morphine without causing morphine-like effects itself³⁴. As seen in Fig 3, naloxone exerts such an effect also on

Fig 1 Inhibition by morphine of the stimulation by PGE₁ of cyclic AMP formation in neuroblastoma clone N4TG3. N4TG3 is a 6-thioguanine resistant mutant²⁰ of a clonal line derived from neuroblastoma C1300 (ref 3). At varying concentrations of morphine, the cells are incubated in the presence and absence of PGE₁. Subsequently, the cyclic AMP formed is measured. *s.d.* are given together with the mean value of three parallel incubations. Data without standard deviations are obtained from single plates. 17.6 $\times 10^6$ cells per plate, passage number 27, viability (exclusion of nigrosin) 96%. *a*, cyclic AMP in cells + medium, 10 $\mu\text{mol l}^{-1}$ PGE₁; *b*, cyclic AMP released into the incubation medium, 10 $\mu\text{mol l}^{-1}$ PGE₁; *c*, cyclic AMP in cells plus medium, no PGE₁.

Fig 2 Inhibition by morphine of the stimulation by PGE₁ of cyclic AMP formation in clonal neuroblastoma N18TG2 \times glioma C6-BU-1 hybrid line 108CC15. A brief description of the cells has been given elsewhere^{18,20}, a detailed report is in preparation. Passage number 14, 5.9 $\times 10^6$ viable cells per plate, viability 85% cyclic AMP in cells, *a*, 3 $\mu\text{mol l}^{-1}$ PGE₁; *b*, no PGE₁.

neuroblastoma cells. The inhibitory effect of 0.1 mmol l^{-1} morphine is abolished by 1–10 $\mu\text{mol l}^{-1}$ naloxone (Fig 3, curves *a* and *b*). Furthermore, in concentrations above 0.1 mmol l^{-1} , naloxone itself causes an elevation of the level of cyclic AMP (Fig 3, curve *c*), and, in combination with PGE₁, potentiates the action of the latter (Fig 3, curve *a*). This effect is even greater when morphine is also present (Fig 3, curve *b*). This result suggests that in the concentration range of 0.1–1 mmol l^{-1} morphine and naloxone are not antagonists but rather act synergistically (Figs 1 and 3). Work is under way to elucidate this phenomenon. In Fig 3, the biphasic shape of curves *a* and *b*, together with the notion that naloxone and PGE₁ increase the levels of cyclic AMP well above that seen when PGE₁ is present alone, indicates two different binding sites for naloxone. The similarity of the effects exerted by morphine and naloxone at high concentrations and their synergism might suggest that the drugs act at the same low affinity binding sites³² and that the specificity of binding is relatively low.

This study adds another item to the increasing list of differentiated nervous functions found in cell lines derived from the nervous system and suggests the suitability of such cells as model system for the investigation of opiate action. In particular, the antagonism between PGE₁ and morphine in the cultured cells parallels strikingly the antagonism observed in intestinal contraction^{25,27,28}. Although in both N4TG3 and 108CC15 the increase of the intracellular levels of cyclic AMP is inhibited by morphine, the hybrid line is more promising as a model system. It is more sensitive to PGE₁ and to morphine than N4TG3. The inhibitory effect of morphine is non-competitive as it is not reversed at high PGE₁ concentrations (30 $\mu\text{mol l}^{-1}$). This is more than 300 times the dose at which PGE₁ elevates cyclic AMP to half maximal value³⁵. Furthermore, not all cell types sensitive to PGE₁ are also sensitive to morphine, as shown in a glioma and glioma \times fibroblast hybrid line³⁵. Like PGE₁, noradrenaline increases the level of cyclic AMP in these cells. Furthermore, this response is not inhibited by morphine. Thus, the antagonistic action of morphine may be restricted both with respect to the cell type and to the hormone affected.

Fig. 3 Naloxone prevents the inhibition by morphine of the cyclic AMP formation stimulated by PGE_1 . 1.61×10^6 viable N4TG3 cells, passage number 29, viability 91%, $3 \mu\text{mol l}^{-1}$ PGE_1 , b , $3 \mu\text{mol l}^{-1}$ $\text{PGE}_1 + 0.1 \text{ mmol l}^{-1}$ morphine, c , without PGE_1 and morphine. The inhibitory effect of morphine in the absence of naloxone is evident, when the points at 0 mol l^{-1} naloxone of curves a and b are compared.

The study of the clonal cell lines sensitive to morphine may have provided a first glimpse at the mechanisms involved in opiate action. The advantage of the system is its simplicity. The cell masses of a clone are relatively homogeneous compared with the complex mixture of cells in brain. Roy and Collier²⁹ studying rat brain homogenates found an adenylyl cyclase which is stimulated by PGE_1 , the stimulation is inhibited by morphine. The use of the cell-free system may be limited by the high background activity of adenylyl cyclase in the absence of PGE_1 and by the very low sensitivity to PGE_1 . The rat brain homogenates are at least 300 times less sensitive to PGE_1 than N4TG3 cells^{29,35}. Nevertheless the major findings—the antagonism between PGE_1 and morphine and the involvement of the adenylyl cyclase system in morphine action—are the same with both approaches and thus the conclusions drawn are similar.

We thank Professor A. Herz for helpful discussion and for naloxone and Dr J. Pike for PGE_1 .

Action potentials induced in slow muscle fibres by partial denervation

Frog slow muscle fibres are usually unable to generate action potentials^{1,2}. It has been demonstrated, however, that this ability is acquired after denervation^{3,4}, and it has been suggested that the inhibitory effect of the small motor axons on the slow fibre membrane results from the release of a 'trophic' substance⁴⁻⁶. Since slow muscle fibres are usually innervated by more than one motor axon⁴, it was important to find out, whether the action potential is induced after partial removal of this 'trophic' influence. Our results show that this is indeed the case.

The experiments were performed on the right pyriformis muscle of *Rana temporaria*. This muscle is usually innervated by spinal branch IX, it has, however, been observed⁷ that occasionally the muscle receives additional motor axons from spinal branch VIII. One of these branches, usually IX, was cut in the pelvis. After the operation the frogs were kept at room temperature (about 19°C), and 11–13 d later the pyriformis muscle was removed, together with its nerve, for

electrophysiological examination⁸. The slow fibres of the piriformis muscle are 10–15 mm long and their length constant is of the same order of magnitude⁹. With a single insertion of the microelectrode measuring potential (about half-way between the tendons), the whole fibre can therefore be explored. Rectangular current pulses were applied to a second microelectrode inserted at a distance of 50–100 μm and the slow fibres were identified by their electrical properties⁹. The nerve was mounted on two pairs of platinum electrodes for stimulation of motor axons and determination of their conduction velocities⁸. Ringer's solution had the following composition (mM): NaCl 110.4, KCl 2.5, CaCl_2 7.2, Tris 5.0. All measurements were performed at 8–10°C.

In all, sixteen muscles were examined after transection of spinal branch IX (14 muscles) or VIII (2 muscles), twelve muscles proved to be completely denervated, while in the remaining four muscles variable proportions of denervated muscle fibres were identified. The slow fibres could be subdivided into three groups. Three fibres (group 1) were completely denervated, presumably because they were originally innervated only by the spinal branch which had been cut, showed action potentials as expected (Fig 1A). Nine fibres (group 2) showed action potentials, generally of smaller amplitude but in contrast to group 1 they responded with an end-plate potential to nerve stimulation (Fig 1B). Three fibres (group 3) were also innervated but did not produce action potentials, and therefore seemed to be normal slow fibres.

Similar results were obtained in a second series of experiments, in which one small branch of the piriformis motor nerve was cut 1–2 mm from its entry into the muscle. Among the 43 slow fibres identified 8–15 d later 26 belonged to group 2, being innervated and yet capable of generating action potentials. Eight fibres were completely denervated and produced action potentials (group 1), while nine fibres seemed to be normal (group 3).

It is important to eliminate the possibility that those slow fibres (group 2) showing both end-plate and action potentials were in the early stage of reinnervation after having been completely denervated. Reinnervation by regenerated motor axons could be excluded, because inspection of the operation site revealed that the proximal and distal nerve stumps were always clearly separated, furthermore there would not have been enough time for regeneration, at least in those experi-

ments in which the spinal branch had been cut. The alternative possibility, that reinnervation of totally denervated fibres had taken place by collateral sprouting from intact axons also seems unlikely in view of the short period (sometimes only 8 d) that had elapsed after the operation. Furthermore the characteristics of the end-plate potentials from the group 2 fibres also suggested that they occurred at residual 'old' end-plates rather than newly formed ones. Thus their amplitudes were usually smaller (mean 18 mV) than normal (30 mV) but not markedly different, and they occurred with normal latencies. Moreover, the majority of fibres (33 out of 35) were innervated by a single slow axon (conduction velocity smaller than 5.2 m s^{-1}).

Our experiments demonstrate that two or more small motor axons are necessary to suppress the action potential mechanism in slow muscle fibres. It is conceivable that each individual axon exerts its effect locally as has been shown for the neural control of acetylcholine sensitivity in frog twitch fibres¹⁴. In this case the transformation of the slow fibre membrane could be restricted to the vicinity of degenerating end-plates, while the membrane remains unchanged near normal end-plates. It may also be that cutting one or more small motor axons leads to a general reduction of the inhibitory effect such that sodium-channels are simultaneously built into the membrane along the entire length of the fibre. At present we cannot distinguish between these two possibilities and more work is needed to understand how the small motor axons exert their 'trophic' effect on slow muscle fibres. It seems clear, however, that a reduction in size of the end-plate potential is not directly responsible because Botulinum toxin markedly reduces the end-plate potential without inducing an action potential¹⁵.

Fig 1 Action potentials (a) and anelectrotonic potentials (b) recorded from a denervated (A) and an innervated (B) slow fibre 9 days after cutting spinal nerve IX. Upper trace, membrane potential, lower traces, membrane currents. Note large membrane time constant typical of slow fibres. c, End-plate potentials elicited in innervated slow fibre by stimulation of spinal nerve VIII at two points 10 mm apart, from the difference in latencies a conduction velocity of 4.4 m s^{-1} was calculated for the motor axon. Both fibres from same muscle. Note also the presence of miniature end-plate potentials in trace b of fibre B.

British anti-Lewisite and organomercury poisoning

2,3-DIMERCAPTOPROPANOL ($\text{CH}_2(\text{OH})\text{CH}(\text{SH})\text{CH}_2\text{SH}$, BALH₃) is generally used in the treatment of mercury poisoning to help remove mercury from the body^{1–3}. It has been reported, however, that use of BALH₃, together with, or shortly after injection into laboratory animals of inorganic mercury^{4–6}, methylmercury^{7–8}, or 'phenylmercury'^{7–9} compounds results in a different initial distribution of mercury in the body than when the compounds are injected alone. For inorganic mercury, the results can be explained in terms of the timing and dosage of BALH₃ (ref. 6). For both methyl and phenylmercury compounds with BALH₃, the mercury content of the brain is greatly enhanced^{7–9}. Although the initial rapid (24 h) distribution of mercury in the animals treated for methylmercury poisoning with BALH₃ is similar to that achieved after 8 d in the absence

of BALH_3 (ref 8), this distribution is undesirable in cases of chronic mercury poisoning where the critical organ is the brain, in which it is metabolised more slowly than in most organs^{10,11}

An understanding of the chemistry involved in the interaction of BALH_3 with mercury compounds, and of the properties of any complexes formed, is necessary to assess these observations. Isolation of $\text{HgBALH}^{1,12}$ has been reported and evidence for the formation of $\text{Hg}(\text{BALH}_2)^{2-}$ (ref 1), $(\text{C}_6\text{H}_5\text{Hg})_2\text{BALH}$ (ref 12) and $(\text{RHg})_n\text{BALH}_{3-n}$ ($n = 1$ (ref 13), 2 (ref 12), $\text{R} = \text{CH}_2\text{CH}(\text{OCH}_3)\text{CH}_2\text{R}'$) has been documented

We have found that reaction of mercuric salts and phenylmercuric acetate with BALH_3 in water leads to precipitation of HgBALH and $(\text{C}_6\text{H}_5\text{Hg})_2\text{BALH}$, respectively

To assist interpretation of physical and spectroscopic data for the complexes (Table 1) we prepared the analogous 1,3-dimercaptopropanol(DMPH₃) complexes

All the complexes are insoluble in water and common organic solvents. Except for HgBALH they dissolve in the coordinating solvents pyridine and dimethylsulphoxide, this may indicate polymeric structures or strong intermolecular forces in the solid state. Assignment of $\nu(\text{Hg-S})$ and $\nu(\text{O-H})$ in infrared spectra of the complexes (Table 1) establishes the basic mode of attachment of mercury to BALH and the loss of two thiol protons on complex formation. Assignment of a coordination number for mercury is, however, not possible since $\nu(\text{Hg-S})$ does not vary greatly with coordination number in related compounds, for example, two-coordinate mercury in $\text{Hg}(\text{SC}_2\text{H}_5)_2$ (ref 14) has $\nu(\text{Hg-S})$ at 330 cm^{-1} , and four-coordinate mercury in *bis* (O-ethylthioacetothioacetato) mercury has $\nu(\text{Hg-S})$ at 362 cm^{-1} (ref 15)

HgDMPH is associated in pyridine (Table 1), consistent with a polymeric or oligomeric structure in the solid state, and HgBALH presumably adopts a similar structure. Molecular weight data indicate monomeric structures for the phenylmercury derivatives in pyridine

Since a variety of 'solvent' environments, for example, aqueous and lipid, are present in organisms, the stability of $(\text{C}_6\text{H}_5\text{Hg})_2\text{BALH}$ in different solvents is of particular interest. In aqueous suspension, $(\text{C}_6\text{H}_5\text{Hg})_2\text{BALH}$ is stable with an excess of BALH_3 since it can be prepared with $n = 2$ (equation (2)); and the possible decomposition products expected, $(\text{C}_6\text{H}_5)_2\text{Hg}$, HgBALH or benzene (gas liquid chromatography), could not be detected. Although stable in pyridine and dimethylsulphoxide (Table 1), addition of acetone to a pyridine solution results in precipitation of HgBALH and formation of diphenylmercury. When $(\text{C}_6\text{H}_5\text{Hg})_2\text{BALH}$ is stirred as a slurry in benzene for 19 h, the insoluble residue contains $(\text{C}_6\text{H}_5\text{Hg})_2\text{BALH}$ and HgBALH , $(\text{C}_6\text{H}_5)_2\text{Hg}$ can be isolated from the solution. Similarly, reaction of phenylmercuric acetate with BALH_3 (2 1) in methanol for 2 h gives a mixture

Table 1 Characterisation of 2,3-dimercaptopropanol (BALH_3) and 1,3-dimercaptopropanol (DMPH_3) complexes*

Complex	Infrared (cm^{-1})†		Molecular weight‡	
	$\nu(\text{Hg-S})$	$\nu(\text{O-H})$	Observed	Calculated for monomer
HgBALH	350	3,325	Insoluble	323
$(\text{C}_6\text{H}_5\text{Hg})_2\text{BALH}$	335	3,330	664 ± 15	678
HgDMPH	353	3,330	500 ± 67 §	323
$(\text{C}_6\text{H}_5\text{Hg})_2\text{DMPH}$	343	3,320	653 ± 43	678
$(\text{C}_6\text{H}_5\text{Hg})_2\text{DMPH} \cdot \text{C}_6\text{H}_5\text{N}¶$	343	—	750 ± 34	757
$\text{C}_6\text{H}_5\text{HgSCH}_2\text{CH}_2\text{OH} $	343	3,230	364	355
$\text{Hg}(\text{SCH}_2\text{CH}_2)_2 $	330	—	330	323

* All complexes have satisfactory elemental analyses ($\text{C}, \text{H}, \text{Hg}, \text{S}$) and, except for insoluble HgBALH , have satisfactory ^1H NMR spectra in both d^5 -pyridine and d^6 -DMSO

† Nujol mulls. All absorptions listed are broad. $\nu(\text{S-H})$ is absent from all spectra, indicating loss of two protons on formation of each complex

‡ In pyridine at 60°C determined by vapour pressure osmometry. Where several determinations were obtained the range is given. Since pyridine is a non-ideal solvent, accurate molecular weights are not expected. However, complex formation with pyridine (see for example ¶ below) as one form of non-ideal behaviour is not expected to affect the accuracy of determinations, since the colligative property determined is the number of molecules formed in solution per solid complex added, and this will not be altered by interaction with the solvent which is present in vast excess

§ These results are intermediate between monomer and dimer, indicating the presence of a monomer-oligomer(s) (most likely dimer) equilibrium. In addition NMR spectra have a very broad methylene resonance, suggesting more than one methylene environment

¶ $(\text{C}_6\text{H}_5\text{Hg})_2\text{DMPH}$ forms a crystalline 1:1 adduct with pyridine. An unaltered $\nu(\text{Hg-S})$ and lowered $\nu(\text{O-H})$ (very broad absorption beneath $\nu(\text{C-H})$ bands at $2,800\text{--}3,200\text{ cm}^{-1}$) indicate that pyridine is hydrogen-bonded to the hydroxyl group, rather than coordinated to mercury. With the hydroxyl group deuterated $\nu(\text{O-D})$ occurs at $2,200\text{ cm}^{-1}$. The calculated molecular weight is that expected for dissolution of a 1:1 mixture of $(\text{C}_6\text{H}_5\text{Hg})_2\text{DMPH}$ and pyridine in pyridine

|| Included for comparison

of $(\text{C}_6\text{H}_5\text{Hg})_2\text{BALH}$, HgBALH and $(\text{C}_6\text{H}_5)_2\text{Hg}$. Thus, with some solvents, $(\text{C}_6\text{H}_5\text{Hg})_2\text{BALH}$ decomposes according to

The formation of diphenylmercury had not previously been suspected and may be an important factor in the distribution of mercury when BALH_3 is administered with phenylmercuric acetate. Diphenylmercury is less polar than Hg^{2+} and $\text{C}_6\text{H}_5\text{Hg}^+$, does not form complexes with neutral ligands¹⁶ and does not react with thiols^{17,18} or BALH_3 at ambient temperature. The toxicity of diphenylmercury does not seem to have been investigated, except for a brief report¹⁹ that diphenylmercury in 'scarcely detectable' concentration, formed by degradation of phenylmercuric acetate (formerly contained in derelict steel drums), was sufficiently toxic to kill fish within a few hours in the Boone Reservoir, Tennessee Valley.

These preliminary results indicate the complexity of antidote action and the need for caution in application of BALH_3 as an antidote for chronic phenylmercury poisoning. This is particularly true before degradation to inorganic mercury, which is substantially complete after 1 d in laboratory animals²⁰⁻²². This study is being extended to include alkylmercury compounds.

Effect of unsaturated fatty acids on the lipid composition of bacteriophage PM2

A LIPID-containing bacteriophage, PM2, provides a simple model to investigate assembly of lipids and proteins into a membrane. The phospholipid in the virion, which is arranged in the form of a bilayer between nucleoprotein core and outer shell¹, has a very different composition from that of the host cell, a marine bacterium, *Pseudomonas* BAL-31 (ref 2). One-third of the viral lipids are derived from lipids synthesised before infection and two-thirds from lipids synthesised during viral replication³.

We have studied the variation in viral fatty acids and phospholipids when the virus was grown in an auxotroph

requiring unsaturated fatty acids, *Pseudomonas* BAL-31, strain UFA (ref 4). The fatty acid composition in host cells and virions varied in a similar manner in media supplemented with different fatty acids, whereas the phospholipid composition of the host cell was almost constant, that of the virion varied depending on the fatty acids used in the media.

Effects of exogenous unsaturated fatty acids on the viral lipid composition were determined using *Pseudomonas* BAL-31, UFA as host. The fatty acid composition in host cells and virions grown in media supplemented with unsaturated fatty acids is shown in Table 1. In media supplemented with palmitoleic (*cis*-16:1) and oleic (*cis*-18:1) acids, the fatty acid composition of phospholipids in virions and host cells seemed to be identical, within experimental error. In medium supplemented with palmitelaidic acid (*trans*-16:1), the amount of palmitic acid (16:0) in virions was larger than that in host cells and the amount of 16:1 in virions was smaller. Virions grown in media supplemented with *cis*-16:1 and *trans*-16:1 had nearly homogenous fatty acid compositions, 16:1 accounting for 89% and 74% of the total fatty acids, respectively. In general, the fatty acid composition in virions reflects that in the host cells and thus can be altered by variation in the exogenous fatty acid.

The phospholipid composition in host cells and virions grown in media supplemented with unsaturated fatty acids is shown in Table 2. In all media except that supplemented with *trans*-16:1, the major phospholipid in virions was phosphatidylglycerol (PG). In medium with *trans*-16:1, phosphatidylethanolamine (PE) became the dominant viral phospholipid. The ratio of PG to PE in viral lipids varied with the input fatty acid. In virions grown on *Pseudomonas* BAL-31 (wild type) in a medium without added fatty acid it was about 1.5, in virions grown on strain UFA in media supplemented with *cis*-16:1 or *cis*-18:1 it was about 1.2, and in virions grown on strain UFA in *trans*-16:1 medium about 0.8. In earlier studies^{2,5} the PG/PE ratio in virus grown on wild type cells in a medium containing the same salts as used above, plus arginine, proline and glucose, was about 2.4. This discrepancy may be the result of differences in the medium used. In contrast to the situation with fatty acids and phospholipids, virions purified from strain UFA grown in the presence of different fatty acids had the same pattern of polypeptides (using SDS-polyacrylamide gel electrophoresis) as those prepared from wild type *Pseudomonas* BAL-31.

For the isolation of fatty acid auxotrophs, *Pseudomonas* BAL-31 was grown at 25°C in AMS salts¹² supplemented with 2 g l⁻¹ of the amino-acid mixture containing 0.1 g l⁻¹ of twenty amino acids (AA medium) and 0.01% oleic acid dissolved in 0.4% bovine serum albumin containing less than 0.05% fatty acids. After ultraviolet irradiation to the 0.5% survival level, fatty acid auxotrophs were isolated using penicillin enrichment in AA medium and replica plating on selective media. A culture (25 ml) of *Pseudomonas* BAL-31 fatty acid auxotroph strain UFA grown in the presence of different unsaturated fatty acids was infected (multiplicity of infection 10) with PM2 which had been grown on wild type cells. This lysate was used to infect 100 ml cultures, which were used in turn for 1 l of culture. Virus was purified from 1 l lysate 3 h after infection⁶. The purity of each virus preparation was controlled by SDS-polyacrylamide gel electrophoresis¹³. Lipids were extracted from purified virus and from host cells which were collected just before infection³. Phospholipids were then isolated on silica gel thin layer plates (Merck, *F₂₅₄*) using diethylether-benzene-ethanol-acetic acid (40:50:2:0.2, v/v). The area corresponding to the phospholipids was made visible with iodine vapour, then scraped and eluted with chloroform-methanol (2:1, v/v). Phospholipid was trans-methylated with BF₃-methanol (14%, w/v, Applied Science Laboratories). Methyl esters were analysed on a Packard model 7620A gas chromatograph with 10% EGSSX on Chromosorb W and 3% SE30 on Gas Chrom Q. Methyl esters were identified by comparison of their retention times with those from a KD ester mixture (Applied Science Laboratories). Results are expressed as percentage composition.

Table 2 Phospholipid composition in *Pseudomonas* BAL-31/UFA and PM2 grown in media supplemented with unsaturated fatty acids

Pseudomonas BAL-31 and strain UFA were grown at 25° C in AA medium with 0.4% bovine serum albumin and 0.01% essential fatty acid. The culture (25 ml) was lysed by PM2 grown on wild type cells. This lysate was used in turn for lysing 100 ml culture containing 3 μ Ci ml⁻¹ ³²P. Virus was purified along with carrier virus grown on wild type cells and its purity was controlled by SDS-polyacrylamide gel electrophoresis, as described in Table 1. Lipids were extracted from virus and host cells, which were withdrawn just before infection as described in Table 1. Lipids were analysed on silica gel thin layer plates (Merck, F₂₅₄) using chloroform-methanol-water (65:25:4, v/v). Each class of phospholipids was detected by exposure to Ilford X-ray film, scraped into vials and counted for radioactivity². Results are expressed as percentage composition.

There are four viral proteins I and II form spikes and outer shell, respectively, III forms the inner shell of the nucleocapsid, while IV is associated with viral DNA (ref. 6). Proteins I, III and IV have isoelectric points at pH 6.2, 5.8 and 5.5, respectively, whereas the isoelectric point of protein II is at pH 12.3. Thus protein II is strongly positively charged at pH 7.0 (refs 7 and 8). The electrostatic interaction between protein II and PG has been suggested as a major factor controlling phospholipid composition and also stabilising the bilayer structure of the completed particle^{7,8}. The PG/PE ratio would remain constant, provided that the fatty acids do not affect the charge distribution and that long range forces play only a minor role. In addition to electrostatic forces, there is evidence for hydrophobic interactions between the bilayer and the inner protein shell as protein III behaves as a proteolipid^{8,9}, and some viral protein(s) seems to penetrate the lipid bilayer and may also participate in lipid-protein interactions.

The physical properties of phospholipids containing different hydrocarbon side chains have been studied using monolayer techniques¹⁰. *Trans*-unsaturated fatty acids have properties intermediate between *cis*-unsaturated fatty acids and saturated fatty acids, forming more condensed films than *cis*-unsaturated fatty acids. Virions grown on strain UFA in the presence of exogenous *trans*-16:1 should therefore have the most condensed lipid bilayer of those reported here, which should lead to a stronger hydrophobic interaction between proteins and lipids within the membrane structure and may thereby overcome the electrostatic interaction. Furthermore, if we compare the known mobility of PE and PG (ref. 11) with the phospholipid composition of virions containing *trans*-16:1, the average fluidity must have decreased. Thus the change in phospholipid composition can hardly be due to a tendency to maintain average fluidity. Although the phospholipid composition in virions varies according to the fatty acid used in the medium, such variations are controlled within narrow limits. Thus both hydrophobic and electrostatic interactions between lipids and proteins probably assist in maintaining viral integrity.

The double helix of tropomyosin

THE tropomyosin molecule consists of two α helices, which form a coiled-coil a little over 400 Å long¹. Besides forming crystals, tropomyosin can be precipitated with divalent cations to produce needle shaped aggregates (showing a variety of patterns of cross striations in the electron microscope²) for which the detailed molecular packings have not been established. At low resolution, however, the α helices may be regarded as smooth rods. The structure of such aggregates could depend, to some extent, on considerations of closest packing of the rods. This possibility seems to have been first considered by Rudall³ in his discussion of the crystal structure of the α protein from Mantis egg case, where he showed that double helices may be close-packed to form sheets by staggering each double helix by one quarter of the pitch with respect to the next. I report here that the idea of a quarter stagger between tropomyosin molecules, in conjunction with certain electron microscope results, leads to a value for the pitch of the tropomyosin helix.

Figure 1a shows an electron micrograph of vertebrate tropomyosin precipitated⁴ with CaCl₂ at pH 8, displaying sets

Fig. 1 *a*, Rabbit striated muscle tropomyosin precipitated with 20mM CaCl_2 at pH 8 *b*, Optical diffraction pattern of (*a*)

of transverse striations repeating axially every 400 Å. A striking feature of the optical diffraction pattern of this form is a prominent 14th order of the 400 Å repeat while the 7th order is weak or absent (Fig 1*b*). This suggests that there is a component in the structure which repeats every 57 Å but which is staggered in alternate units by one half of this distance. This suggestion has also been made by Parry and Squire⁵ who noticed that the electron micrographs of this form of tropomyosin show subperiods of about 28 Å and that "the separation of bands related by twofold symmetry is always an odd multiple of 28 Å".

These observations lead to the hypothesis that the pitch of the double helix in tropomyosin is 114 Å, in which case the repeat distance in the molecule would be 57 Å (the half-pitch), close packing would halve this to give a repeat in the sheets of 28.5 Å. The sheets could then superimpose, forming the observed structures. (The various ways in which such sheets can pack together to form three dimensional structures will be discussed elsewhere.) Accumulation of negative stain between the helices would then produce the subperiods observed with the electron microscope.

In the living muscle, tropomyosin is associated with actin which consists of two strands of subunits repeating along a helix with pitch of about 700 Å. Tropomyosin molecules lie in the two grooves, one on each side of the actin helix, and each molecule appears to interact with one strand. The vertical distance between the subunits of actin is about 55 Å. The distance along the helix between the subunits at the radius at which tropomyosin lies, is, however, close to 57 Å. (These findings have been summed up by Huxley⁶.) Thus, if the pitch of the tropomyosin double helix were 114 Å, each actin subunit would be in a position to interact with one half-turn of this helix. In this case, the chemical sequence of tropomyosin would be expected to display a similar periodicity, since each half-turn would have a similar chemical function to perform. An indication of such periodicity has recently been pointed out by Parry⁷ for the partial sequence of tropomyosin published by Hodges *et al.*⁸ Parry observed a pseudo-repeat of about 29 Å in the various types of residue groupings along the chain, so that each successive pair of these groups would lie opposite one actin subunit. Only if the pitch of the tropomyosin double helix were commensurate with the actin periodicity, however, could the repeating groups face towards the actin subunits to present to each a similar aspect.

Reaction of ribonucleosides and deoxynucleosides with copper(II) acetate

BERGER *et al.* reported¹ that ribonucleosides and deoxynucleosides can be differentiated by their effects on the optical spectra of copper(II) acetate in dimethylsulphoxide (DMSO). They suggested that the 2' and 3' oxygen atoms in ribonucleosides bridge pairs of copper atoms, forming 1:1 copper(II) acetate/ribonucleoside complexes.¹ We have examined the species in such solutions by EPR. Optical spectra are not ideal as the bands are broad, and components of mixtures cannot readily be resolved. EPR spectra of spin-coupled ($S = 1$) copper(II) dimers differ appreciably, however, from those of monomeric ($S = \frac{1}{2}$) compounds. Moreover, they are sensitive to the nature of the bridges²⁻⁵ and to the symmetry about the Cu-Cu axis. Our conclusions from these studies differ from those obtained previously.¹

The X-band spectra of frozen DMSO solutions of copper(II) acetate alone and with various ribonucleosides and deoxynucleosides are shown in Fig 1. As in previous work¹ fresh solutions were used (10^{-2} M in copper(II) acetate). The $S = 1$ bands at about 40, 460 and 590 mtesla (mT) (Fig 1*a*) confirm that copper(II) acetate is dimeric in DMSO. The spectrum of a 1:1 copper(II) acetate dimer/uridine solution (Fig 1*b*) shows that uridine cleaves the dimer forming a large amount of a monomeric copper(II) species, with a strong signal at about 300 mT. There is no evidence for a dimer containing ribonucleoside bridges, which would give new $S = 1$ bands. Moreover, the presence of both acetate and ribonucleoside bridges would result in $E \neq 0$ and a split H_{xy} band.⁶ Instead, the residual $S = 1$ spectrum is that of copper(II) acetate.

The spectrum of copper(II) acetate and deoxyuridine (Fig 1*c*) shows that, in contrast to conclusions drawn¹ from optical spectra, the deoxynucleoside also cleaves the dimer, but to a lesser extent than uridine under the same experimental conditions. Deoxythymidine gave similar results. Both cytidine and deoxycytidine cause appreciable rupture of the dimer (Fig 1*d*). Deoxycytidine is more effective in this respect than deoxyuridine or deoxythymidine. The spectrum with cytidine differs significantly from that with uridine in the g_{\parallel} region of the monomer. Whereas the monomers formed by uridine, deoxyuridine and deoxythymidine each show one set of g_{\parallel} bands (Fig 1*e*), with cytidine (Fig 1*f*) there are two sets of g_{\parallel} components ($A, g_{\parallel} 2.304, A_{\parallel} 15 \text{ mT}$, $B, g_{\parallel} 2.249, A_{\parallel} 17.5 \text{ mT}$) indicating the presence of two monomeric species.

These results suggest that differentiation between ribonucleosides and deoxynucleosides by copper(II) acetate does not result from bridging by the 2' and 3' OH groups, but from the relative ease with which the dimeric structure is broken. Assuming complete protonation of N(3) in deoxyuridine and uridine, the major donor sites will be the sugar hydroxyl groups. Coordination of the 2' or 3' OH group of uridine to the terminal position of copper(II) acetate favours formation of a chelate ring by displacement of a neighbouring carboxylate oxygen by the other OH group of the ribonucleoside. Rupture of one acetate bridge would be followed by complete break-up of the dimer. As this mechanism is not available to deoxyuridine or deoxythymidine a differentiation between ribonucleoside and deoxynucleoside becomes possible.

We have observed, however, that deoxynucleosides also cause some rupture of the dimer. A possible reason is suggested by the results obtained with cytidine and deoxycytidine. Coordination of the non-protonated nitrogen, N(3), in cytidine

Fig. 1 X-band EPR spectra of frozen DMSO solutions of *a*, copper(II) acetate, *b*, copper(II) acetate and uridine (1 dimer 1 nucleoside), *c*, copper(II) acetate and deoxyuridine (1 dimer 1 nucleoside), *d*, copper(II) acetate and cytidine (1 dimer 1 nucleoside), *e*, as *b*, but showing the g_{11} bands of the $S=\frac{1}{2}$ spectrum in more detail, *f*, as *d*, but showing the g_{11} bands of the $S=\frac{1}{2}$ spectrum in more detail

and deoxycytidine to the terminal position in copper(II) acetate would bring the oxygen on C(2) and the amine group on C(4) close to acetate oxygen atoms and thus destabilise the dimer. With deoxycytidine this would be the main mechanism as there is no 2' OH group. With cytidine, however, either mechanism, that is, chelation by 2' and 3' OH groups or coordination by N(3), could operate. This would account for the two monomeric species observed. In polar solvents the N-H proton in deoxyuridine and deoxythymidine could undergo keto-enol tautomerism. Copper(II) acetate would displace this equilibrium towards the enol form by coordinating the non-protonated N(3) atoms. This would enable deoxyuridine and deoxythymidine to interact with copper(II) acetate, though to a smaller extent than deoxycytidine, as observed.

We conclude that copper(II) acetate does not 'recognise' the difference between ribonucleosides and deoxynucleosides by serving as a template for ribonucleoside bridges. Instead, the factors involve competing influences of the various co-

ordinating groups present, and in a broader biological context these influences will vary with the metal ion^{7,8}.

Statistical significance of DNA sequence symmetries

SOME regions of DNA involved in regulatory or catalytic interactions with proteins have sites with twofold rotation symmetry in the primary nucleotide sequence¹⁻³. It would be worthwhile to determine whether certain of these symmetries occur so rarely by chance that they probably have a function, for example, as recognition sites for symmetric protein complexes. Likewise, it would be useful to be able to dismiss other apparent symmetries as probable statistical accidents of no functional importance. The following quantitative method can be used to evaluate the statistical significance of hyphenated (that is, incomplete) symmetries, where a more intuitive approach may be misleading. Since the probability of random occurrence of a given subsequence increases in almost direct proportion to the length of the sequence considered, a rigorous approach will become increasingly important in the evaluation of the significance of subsequence anomalies occurring in the much longer DNA sequences that will be determined in the future.

Rotation symmetry is said to exist in a DNA site if rotation about a twofold axis at the centre of the site and perpendicular to the DNA helix axis does not change the structure of the site. Various rotationally symmetric sites in bacteriophage λ DNA in the region of the joined cohesive ends (*cos*) and the region of repressor binding are indicated in Fig. 1. These symmetries are imperfect, and not all positions in the sites are invariant under rotation. The base pairs in these sites to be evaluated for symmetry have been marked *s*, *p* or *h* to designate whether under the rotation symmetry transformation they remain invariant (*s*), change but retain the same purine-pyrimidine orientation (*p*), or do neither of the above (*h*). The λ *cos* site designated in Fig. 1a has five perfect symmetries (*s*), five purine-pyrimidine symmetries (*p*), and one hyphen (*h*). A site with this extent of symmetry will be designated by the notation ($S_5P_5H_1$). Obviously, there is some probability that this symmetry could have arisen entirely by statistical accident. In a random sequence of 50% GC base composition, the *a priori* probability of an isolated occurrence of an *s* is 1/4, of a *p* is 1/4, and of an *h* is 1/2, so the *a priori* probability of the symmetry ($S_5P_5H_1$) in a sequence of length 2 ($S+P+H$) is

$$\frac{(S+P+H)^1 (1/4)^5 (1/4)^5 (1/2)^1}{S^1 P^1 H^1}$$

Fig 1 Symmetrical sites in certain regions of λ DNA. Bracketing lines indicate the two halves of a site symmetrical about a twofold rotation axis positioned at the symbol showing a dot within a circle. The symbol | designates the positions in λ *cos* at which single strand nicks must be introduced to generate cohesive ends. Other symbols are explained in the text: *a*, λ *cos* region (region of joined cohesive ends)³⁻⁵, 5_5s_{p1h} symmetry site, *b*, region of λ repressor binding¹, 8_3s_{p1h} symmetry site, *c*, region of λ repressor binding¹, 7_3s_{p3h} symmetry site, *d*, region of λ repressor binding¹, 7_6s_{p2h} symmetry site

The factorial coefficient arises because the order in which the various symmetries would occur in the site was not specified beforehand, so all significant permutations must be counted.

When a region of DNA is examined for sequence symmetries, the intention is usually to note all sites with sufficient symmetry to be of interest, rather than only sites of one specified degree of symmetry. Hence a satisfactory criterion for regarding an observed sequence to be exceptionally symmetrical is provided, not by the probability of occurrence of the symmetry, but rather by the probability that a random sequence of equal length would have an equal or greater symmetry.

The *a priori* probability, E_p , that at least M out of N positions in a site are either purine-pyrimidine symmetrical (p) or perfectly symmetrical (s) is

$$E_p = \sum_{i=M}^N \sum_{j=0}^i \frac{N! (1/4)^j (1/4)^{i-j} (1/2)^{N-i}}{j! (i-j)! (N-i)!}$$

$$= (1/2)^N \sum_{i=M}^N \sum_{j=0}^i \frac{N! (1/2)^i}{j! (i-j)! (N-i)!}$$

which is obtained by summing the individual probabilities of all such sites. Similarly, the *a priori* probability, E_s , that at least M positions in a site of length N are purine-pyrimidine symmetrical or perfectly symmetrical, and of these at least R positions are perfectly symmetrical is

$$E_s = (1/2)^N \sum_{i=M}^N \sum_{j=R}^i \frac{N! (1/2)^i}{j! (i-j)! (N-i)!}$$

The latter quantity, E_s , is of greater interest because it can be assumed that perfect symmetry will be more important than purine-pyrimidine orientation symmetry in most DNA recognition schemes, but the expectation of the symmetry can be shown to increase to E_p when the base composition of the region investigated is biased, for independent reasons, very heavily towards either GC or AT. For evaluation of an $(S_pP_pH_h)$ symmetry, the appropriate values of M , R and N in the above expressions are given by $M = S+P$, $R = S$, $N = S+P+H$. The expressions are most conveniently evaluated by computer.

The values of E_p and E_s for the sites shown in Fig 1 are tabulated in columns 3 and 4 of Table 1. These values reveal

Table 1 Symmetry and statistical significance of sites shown in Fig 1

Site illustrated	Rotation symmetry type	E_p , per-site probability of greater or equal purine-pyrimidine symmetry	E_s , per-site probability of greater or equal total symmetry	No. of sites of similar length in region considered	Expected frequency of sites of greater or equal total symmetry in region considered
Fig 1a	5_5s_{p1h}	5.86×10^{-3} = 1/171	3.70×10^{-3} = 1/270	—	—
Fig 1b	8_3s_{p1h}	3.17×10^{-3} = 1/315	3.79×10^{-4} = 1/2637	19	0.007
Fig 1c	7_3s_{p3h}	4.61×10^{-2} = 1/22	9.29×10^{-3} = 1/108	19	0.177
Fig 1d	7_6s_{p2h}	3.69×10^{-3} = 1/270	1.90×10^{-3} = 1/526	11	0.021

Column 2 indicates the symmetry type of the site according to the notation introduced in the text. Columns 3 and 4 give the rarity of occurrence of at least this degree of symmetry in a single site. Column 5 gives the number of such sites that can be tested for symmetry in the region under consideration, and the value in column 6, the product of values in columns 4 and 5, gives the expected frequency of occurrence of a site showing at least this degree of symmetry in the whole region under consideration.

that only about one sequence in 200 of length 22 would show at least the $(5_s, 5_p, 1_h)$ symmetry observed in the λ *cos* site. It would seem likely that this symmetry reflects some underlying mechanism. The significances of the symmetries at sites in the repressor-binding region of λ DNA vary considerably. When considered alone, these sites all appear to be quite rare, but this is misleading. If λ cohesive ends are generated by a symmetrical recognition-catalysis complex, the symmetry axis should, as it does, lie equidistant from the two sites at which nicks are to be introduced (Fig 1a). There is no such *a priori* basis for site selection, however, in the case of the λ repressor-binding region. Symmetries were considered wherever found. If the symmetry axis lies either on a base pair (as in Fig 1b) or between two base pairs (as in Fig 1c), then the number of sites comprised of two sequences of length N separated by zero or one base pair which can be tested for symmetry in a total sequence of length L is given by $2L-4N+1$. When each per-site expectation of symmetry is multiplied by the number of available sites, the results (Table 1, column 6) reveal that sites having at least $(8_s, 3_p, 1_h)$ symmetry, or $(7_s, 6_p, 2_h)$ symmetry, would be expected to occur in regions of 35 base pairs with a frequency of 0.7%, or 2%, respectively, but that sites having at least $(7_s, 3_p, 3_h)$ symmetry would be expected to occur with an 18% frequency. Hence the symmetries shown in Fig 1b and d would seem likely to be functionally significant, but the symmetry of Fig 1c could well be due to chance.

It can be shown that in a random DNA sequence the occurrence of symmetry about one rotation axis does not affect the probability of symmetry about a second, distinct axis (my unpublished work). Two sites symmetrical about different axes can therefore be considered independently, even if the sites overlap. This independence does not generally hold for more than two overlapping sites.

The lack of statistical significance in the observation of a symmetry does not necessarily imply that the symmetry is not functionally significant. Trial calculations reveal that it may be impossible to distinguish statistically certain functional symmetries from spurious symmetries unless the region under consideration can be restricted independently to considerably fewer than 100 base pairs.

This analysis determines the position of an observed symmetrical site in the symmetry-ordered distribution of only those sites which are of the same length. Although this comparison is limited, it provides an easily-computed estimate of the rarity of the symmetry. A similar approach could be used in the statistical evaluation of other types of sequence anomalies such as purine-pyrimidine orientation bias.

Single-stranded regions in DNA of old mice

INVESTIGATIONS have shown that senescence is accompanied by molecular changes in the structure of the eukaryotic genome. Some of these changes have been reported to result in the loss of some genetic material in the brain cells of ageing beagles¹. Furthermore, the molecular weight of rat liver DNA decreases as a function of senescence². If such changes occurred on a large scale, the resulting genetic damage could affect severely some of the crucial gene functions of an organism. We are

studying the physical state of the DNA of senescing mice, and report here the accumulation of an increasing amount of single-stranded regions in the DNA with age.

DNA was isolated from the livers of 1, 6, 15, 20, 25, and 30-month-old CBF₁ mice (Charles River Breeding Laboratories). Single-strand-specific nuclease *S*₁ was used to investigate the presence of single-stranded regions in the native DNA of mice of different ages. Figure 1 shows the absence of nuclease *S*₁ sensitivity in the DNA of mice aged 1-15 months. That of mice 20 months of age or older was increasingly sensitive to the enzyme, which digested 14-25% of it. We cannot rule out the possibility that this sensitivity began before the mice were 20 months old, since we did not test the DNA of 15-20-month-old mice. These results are based on three experiments in each of which the DNA from different animals of the same age group were used.

There are already two sets of indirect evidence for single-stranded regions in the DNA of ageing animals. Samis *et al*³ reported increased incorporation of ³H-thymidine into the nuclear DNA of senescent rats in the absence of a corresponding increase in mitotic index. This implies that the thymidine, after conversion to dTTP, was used in the repair of nuclear DNA. Calf thymus DNA polymerase has been shown to catalyse a greater incorporation of DNA precursors into the nuclei of old mouse neurones, astrocytes, Kupffer cells and heart muscle fibres⁴. This reaction is known to require single-stranded regions of primer DNA along which the complementary strand can be synthesised⁵. Presumably these single-stranded regions of the DNA from senescent mice were hydrolysed by nuclease *S*₁ in our experiments.

As we do not know the ultimate fate of the nuclease *S*₁-sensitive regions in the DNA of old mouse liver, we suggest that

Fig. 1 Nuclease *S*₁ digestion of 1-30-month-old mouse liver DNA. DNA was prepared essentially by the method of Marmur³ except that a phenol-chloroform (1:1) mixture was used for extracting the proteins. Nuclease *S*₁ was prepared from *Aspergillus oryzae* crude α -amylase (Sigma) by the method of Sutton⁴. The reaction mixture consisted of 30 μ g of native or heat-denatured DNA, and 10 μ g nuclease *S*₁ all in 1.5 ml of KZS (0.1 M KCl, 0.1 mM ZnSO₄, 0.025 M sodium acetate pH 4.5). Incubation was at 37°C for 30 min. After chilling, 25 μ g of carrier calf thymus DNA was added followed by 0.5 ml of 2 N perchloric acid. The control system (1.5 ml) consisted of 30 μ g of liver DNA, 10 μ g enzyme in KZS to which 25 μ g carrier DNA and 0.5 ml of 2 N chilled perchloric acid were added without incubating. The acid-insoluble material was collected by centrifuging at 17,000 rpm for 20 min. The A_{260} of the supernate was measured. The amount of DNA rendered acid-soluble by nuclease *S*₁ was obtained by subtracting the A_{260} of the control supernate from that of the corresponding experimental sample. This value represented the amount of DNA digested by nuclease *S*₁ and was used to calculate the percentage of hydrolysed DNA. ●, Native DNA, ○, denatured DNA.

Fig 2 Postulated model of the regions of nuclease S_1 attack on the DNA of senescent mice: DNA with single-stranded region (a) terminally located, and (b) internally located, (c) cross-linked DNA with single-stranded regions in the junction region. Arrows indicate points of possible nuclease attack.

the formation of regional single-stranded stretches in the DNA of senescent animals represents a transitional stage in the process leading to the elimination of nucleotide sequences that are to be discarded¹. Figure 2 shows models of the possible structures of the regions in DNA attacked by nuclease S_1 . There may be many areas of nuclease S_1 attack on crosslinked DNA molecules of which we present a simpler model in Fig 2c. The metabolic significance of the existence of single-stranded regions in the DNA of older mice remains unknown. These regions may be the result of increased nuclease activity coinciding in time with a senescence-associated decline in repair enzyme activity in the cells. Loss in enzyme activity during senescence has been observed in other systems⁸. Thermodynamically, this has the advantage of making the energy previously reserved for repair functions available for hydrolytic processes. If the defective regions of the DNA occur in the genes for constitutive functions and are not repaired at the appropriate time, the biochemical lesions in the metabolic pathways of the particular cells are likely to result in the death of the organism, the harm can be particularly severe in the cells of non-replenishing tissues such as those of the muscular and nervous systems.

We thank the University of Michigan for grants and the National Institute of Child Health and Human Development for mice.

Is mRNA transcribed from the strand complementary to it in a DNA duplex?

We have tested the assumption that the messenger RNA sequence is uniquely determined by the DNA sequence complementary to it. Because RNA is usually transcribed from a DNA duplex, there is the possibility that the DNA strand that is not complementary to the mRNA influences the RNA base selection. This possibility exists in models that postulate like-with-like base pairs¹⁻³, triple helix models of DNA-DNA-RNA⁴, triple base interactions such as those described in tRNA⁵, and models in which RNA polymerase may confer a special type of specificity (non-Watson-Crick) to RNA base-DNA duplex interactions, as well as in experiments in which separated are compared with non-separated strands⁶⁻⁷.

The logic of our experiment is as follows. If one makes DNA heteroduplexes in which one strand has the coding for the premature termination of a given protein, while the other has the coding for the complete protein, and then uses these heteroduplexes as templates for transcription-translation in a coupled⁸ cell-free protein synthesizing system, then one can ask, by fractionating the radioactive protein products on Ornstein-Davis⁹⁻¹⁰ acrylamide gels containing SDS, which product is made—the complete protein, a fragment or neither? If coding for RNA synthesis were solely a function of the nucleotide sequence of only one strand of a DNA duplex, then no matter

Fig 1 Autoradiograph of urea SDS-Tris-glycine acrylamide gels showing the *in vitro* protein products stimulated by various homo- and hetero-duplex DNAs. Gene products were identified as described before¹⁸ and are marked with Roman numerals. DNAs used as template for incorporations shown in (a), (b) and (h) were homoduplex (had not been subjected to cleavage, denaturation and renaturation). DNAs used were (a) WT homoduplex, (b) amber IV₁₂ and VII homoduplex, (c) amber IV₁₂ and VIII +, WT -, (d) amber IV₁₇ +, WT -, (e) WT +, amber IV₁₂ and VII -, (f) WT +, amber IV₁₇ -, (g) background (no added DNA: the bands reflect the synthesis of *E. coli* proteins from endogenous message), (h) amber IV₁₇ homoduplex, showing prominent fragment produced when this DNA is used as template. DNA was isolated as described before¹⁸. Heteroduplex molecules were constructed by cleaving RFI with endonuclease R *Hind*, isolating the cleavage products on sucrose gradients, denaturing the product in alkali, annealing to a 20-fold molar excess of the appropriate phage (+) strand DNA, and re-annealing at 65°C for 1.5 h, as described by Vovis *et al.*¹³⁻¹⁴. The circular reannealed molecules were purified by neutral sucrose gradient centrifugation and used as templates in the coupled transcription-translation system. All subsequent steps were as described previously¹⁸.

Fig. 2 Densitometer tracing of an autoradiograph of protein products programmed by heteroduplex DNA of composition +, wild type, -, amber IV (lower tracing), +, amber IV, -, wild type (upper tracing). Other details are as described in Fig. 1. The arrow marks the position of the gene IV product.

which or how many termination signals were on the other strand a complete protein would be made from at least one of the two possible heteroduplexes. Furthermore, if the results indicate that only one strand actively codes for RNA and the resultant protein, one can determine which strand is active.

To test these hypotheses, we constructed heteroduplex DNA molecules using coliphage ϕ 1 DNA. RNA transcribed from this DNA, both *in vivo* and *in vitro*, is complementary to only one of the DNA strands, the non-phage or (-) strand¹¹⁻¹². The heteroduplexes were constructed by annealing plus strands obtained from phage with minus strands obtained from intracellular double-stranded-replicative form DNA (RFI) as described by Vovis *et al.*¹³⁻¹⁴. Six types of heteroduplexes were constructed using two distinct gene IV amber mutants, these heteroduplexes included all permutations of amber and wild type genes in both plus and minus strands.

As Figs 1 and 2 show, complete proteins are synthesised by the coupled transcription-translation system whenever the minus strand of the heteroduplex is wild type with regard to gene IV. When the minus strand contains a gene IV amber mutation, the gene IV product is not made. Because of intrinsic sensitivity limitations of the assay system, we would not have been able to detect effects on protein synthesis comprising less than 10% of the wild type control.

These results thus support the hypothesis that the information for RNA transcription of structural genes is not strongly affected by a single base change in the duplex strand not complementary to the mRNA synthesised. We do not know what the effect of other sorts of changes would be.

All of the heteroduplex molecules were constructed by a method which includes the use of endonuclease R *Hind* to cleave ϕ 1 RFI. This endonuclease makes a single, unique double strand break in this DNA¹⁵, which is located within gene II¹⁶⁻¹⁷. Such cleaved DNA does not act as template for the synthesis of gene II protein *in vitro*¹⁸. It is interesting then, that some gene II product was synthesised in reactions primed by the circular heteroduplex DNA molecules which initially contained a single-stranded break within gene II. This suggests that transcription may not be affected by the presence of a nick in the template strand, although further experiments are needed to establish the point firmly.

This experiment was designed to test the transcription rules for structural genes coding for proteins, and showed that only the template strand seems to be significant DNA which is

heteroduplex in regions corresponding to promoters, operators or transcription termination regions might not function normally, since in these instances DNA-protein recognition is quite likely to involve both strands of a duplex, and there is no *a priori* reason to think that function is limited to one strand.

Template activity of ϕ 1 RFI cleaved with endonucleases R *Hind*, R *Eco*P1 or R *Eco*B

ENDONUCLEASE R *Hind* makes a single, unique, double-stranded break in the double-stranded circular DNA (RFI) which can be isolated from bacteria infected with bacteriophage M13 (ref. 1), ϕ d (refs 2 and 3), or ϕ 1 (Horiuchi and Zinder, unpublished observations). We wish to report that ϕ 1 RFI cleaved by endo R *Hind* acts as a template for protein synthesis in a coupled *in vitro* transcription-translation system⁴, and that with the exception of the product of gene II of ϕ 1, the normal complement⁵ of *in vitro* phage-specific proteins is made. No prominent new polypeptide is observed (Fig. 1), this suggests that a substantial fragment of the gene II product is not coded for by RFI cleaved with endo R *Hind*. In addition, neither the size nor the relative yield of the product of the proximal gene^{5,6}, gene IV, is affected. This implies that the break is likely to be in a region extending from the C-terminus of gene IV to the N-terminal portion of gene II. A similar location has been assigned to this break with the use of entirely different methods by Seeburg and Schaller⁷.

Endo R *Hind* is one of a class of endonucleases which cleave DNA at specific sites and do not require a specific cofactor^{8,9}. The full length, linear, double-stranded DNA

Fig. 1 Autoradiographs of urea-Tris-glycine-SDS acrylamide gels showing the protein products synthesised *in vitro* in a coupled system⁴ with the use of f1 RFI (a), f1 RFI cleaved with endonuclease R *Hind* (b), or with endonuclease R *Eco*PI (c), or with endonuclease R *Eco*B (d). A background incorporation (no added DNA) is shown in (e), and is to be compared with (d) only. Roman numerals identify gene products, as in ref. 5 (a), (b) and (c) are from the same gel slab, (d) and (e) from a different gel slab. In (d) the coat protein, product of gene VIII, has migrated close to or at the front, and is not readily distinguishable from it. RFI was prepared as before⁵, subjected to cleavage as detailed in the legend to Fig. 2, and used as a template as described before⁵. Electrophoresis, autoradiography and so on were as described before⁵. O marks the origin, F the front.

Fig. 2 Autoradiograph of a 14% agarose gel showing a, Three fragments generated from f1 RFI by endonuclease R *Hae*III, as DNA size markers. The size of each fragment is calculated from its relative content of ³²P, and is expressed as a percentage of the total f1 genome. Fragment sizes from Horiuchi, unpublished; b, Endo R *Hind* cleavage product of f1 RFI previously cleaved with endo R *Eco*PI (RFIII/PI); c, f1 RFI cleaved with endo R *Eco*PI only; d, f1 RFI cleaved with endo R *Hind* only; e, Untreated f1 RFI (the upper band is contaminating RFII). Cleavage reactions with *Haemophilus* endonucleases were carried out as follows: a 20 µl reaction contained 7 mM Tris-HCl, pH 7.4, and 7 mM MgCl₂, 0.2 µg ³²P-f1 RF and either 0.6 µg endo R *Hae*III or 1.3 µg endo R *Hind*. Incubations were at 37°C for 1 h. Reactions were stopped by adding 50 mM EDTA-0.25% SDS and the mixture was analysed by electrophoresis on 14% agarose gels¹². Cleavage reactions with endo R *Eco*B and R *Eco*PI were carried out as described before¹⁰ and the RFIII generated in these reactions was isolated and purified as described¹⁰. The RFIII was dialysed against 0.05 M Tris, 0.05 M NaCl, 0.001 M EDTA, pH 7.4, concentrated under a stream of N₂ gas, precipitated with 3 volumes of 95% ethanol, redissolved in the above buffer and used either as template for protein synthesis or as substrate in further restriction enzyme reactions.

Fig. 3 Densitometer tracing of an autoradiograph of a 4% acrylamide gel slab on which the products generated from ³²P f1 RFI by the action of endo R *Eco*PI and R *Hind* had been subjected to electrophoresis. The origin is marked O, the direction of electrophoresis is from left to right. Larger fragments stay at or near the origin, smaller ones migrate into the gel. The arrows indicate the position at which fragments generated by endo R *Hae*III migrated in another slot of the same gel. The numbers under the arrows refer to the sizes of these marker fragments, expressed as a percentage of the f1 genome. All other conditions were the same as those in Fig. 2, and the material placed on the gel was the same as that shown in Fig. 2b. Gels were prepared and run as described by Danna *et al.*¹³

(RFIII) produced from f1 RFI by the action of endo R *Hind*, when denatured and subsequently reannealed, remains a linear, full length molecule¹. We have previously shown¹⁰ that in the presence of S-adenosyl methionine and ATP, endo R *Eco*B and R *Eco*PI also yield full length linear molecules as their primary product, but, in contrast to those produced by endo R *Hind* these molecules form circular structures upon denaturation and renaturation. This observation suggested that the sites of cleavage of these latter enzymes are not unique, even though only one double-strand break is introduced into any particular molecule¹⁰.

It was interesting, then, to use f1 RFIII produced by these enzymes as templates for the coupled system. As Fig. 1 shows, endo R *Eco*PI, like endo R *Hind* creates an RFIII which is no longer able to act as template for the synthesis of gene II product. DNA cleaved by endo R *Eco*B seems still to code for the normal complement of f1 *in vitro* proteins, but at much reduced efficiency. In view of the postulated heterogeneity of the cleavage sites for endo R *Eco*PI (ref. 10), the specific absence of gene II protein was rather surprising. Our dilemma was resolved, however, by examination of the cleavage products obtained when RFI is treated both with endo R *Eco*PI and R *Hind*. Figure 2 shows that stepwise treatment of f1 RFI with endo R *Eco*PI and then endo R *Hind* generates a primary product which is not distinguishable, in mobility on 14% agarose gels, from that produced by endo R *Hind* alone. Longer exposure of the autoradiographs shows that in addition, two minor components are found as products of the combined cleavage, one comprising some 70% and the other about 30% of the genome. When the products of the stepwise cleavage are analysed on 4% acrylamide gels, which resolve smaller fragments, four additional fragments are observed which range in size between 4 and 16% of the f1 genome (Fig. 3). We interpret these results to mean that most of the endo R *Eco*PI mediated breaks occur at positions which are within a distance of 4 to 16% from the site of the endo R *Hind* break. The other cleavage products of the combined action of the two enzymes, those ranging in size from 84 to 96% would not be readily

distinguishable from the full length RFIII in the agarose gels (Fig 2) From the protein synthesis data, we infer that most of the endo R *Eco*P1 breaks occur within gene II, which spans, at a minimum, some 20% of the f1 genome⁵ The site which gives rise to the 70 and 30% fragments is most probably not within gene II

Takanami¹¹ has demonstrated that *in vitro* transcription of fd RFI leads to at least four well defined transcripts Use of fd RFI cleaved by endo R *Hind* diminished the size of the two larger transcripts, but did not affect the size of the two smaller² These results of Takanami², which we have confirmed, together with the data presented here, suggest that only the larger of the RNAs participate in the synthesis of gene II protein

Induction of dominant lethal mutation in male mice by ethyl alcohol

THERE have been many studies of the effects of ethyl alcohol on reproductive performance and of the genetic aspects of this relationship¹⁻¹⁰ But in spite of extensive investigations of the genetic determination of alcohol preference in experimental animals, there has been little research on other genetic aspects of alcohol consumption¹¹⁻¹³ It has been assumed for a long time that alcohol presents no genetic hazard Using the dominant lethal technique, we have now found that in mice ethyl alcohol can be mutagenic when given under certain conditions

We carried out three experiments to investigate the mutagenic role of ethyl alcohol in male mice In the first (done in the Department of Genetics, University of Cambridge, England) eight 10-week-old CBA/Fa Cam male mice were given 0.1 ml of 40% ethyl alcohol (1.24 g g⁻¹) by polyethylene gastric tube once a day for 3 consecutive days

Fig 1 Effect of ethyl alcohol on litter size sired by treated males ○, control, △, treated

Each mouse was then caged with a virgin, untreated female of the same strain On the seventh day the males were transferred to cages with different virgins Five treated males were allowed to mate with new females at weekly intervals until the sixth week Pregnant females were allowed to produce their first litters, the size and sex ratios of which were recorded The young were examined for morphological abnormalities Several matings of the breeding colony were set up at the same time and in the same way but without alcohol treatment, to serve as a control

In our second experiment (carried out at the Worcester Foundation for Experimental Biology) mice of the inbred strain CBA/J (Jackson Laboratory) were tested for mutagenicity of ethyl alcohol using the dominant lethal test Mice were raised at the Worcester Foundation from the age of 7-10 weeks before use Two groups of male mice were given ethyl alcohol by gastric tube as before In one group, 13 males were treated with 0.1 ml of 40% alcohol daily for 3 consecutive days The second group of six males were each treated as above but with 0.1 ml of 60% (1.88 g g⁻¹) alcohol The eight control males were each given 0.1 ml of distilled water After the third treatment, each was mated to two CBA/J females and to further females after 3 d Each male was allowed to mate with new females seven more times at 4-d intervals The results of such a mating schedule would reflect the differential response of the different maturation stages of the germ cells

Successful matings were established by observing the formation of the vaginal plugs Pregnant females were killed and dissected 13-15 d after conception Corpora lutea and

*Dominant lethal mutation index

$$= \left[1 - \frac{\text{Litter size per experimental female}}{\text{Litter size per control female}} \right] \times 100$$

†t test for comparison between experimental and control values ($t=3.145$, $P<0.01$)

dead and live implants were scored for each pregnancy. Dead implants refer to early deaths. Late embryonic deaths were included with the live implants. The frequency of induced dominant lethal mutations was calculated according to Ehling *et al.*¹⁵

To assess the reproducibility of our results we repeated the second experiment, testing the effect of only one dose of alcohol, using CBA/J mice. Twelve males were treated with 40% alcohol. Twelve control mice received water instead of alcohol.

The size of full term litters obtained in the first experiment gives an estimate of the induction of dominant lethals as shown in Table 1. The number of live born approximates closely the number of live implants observed at mid-pregnancy except for late deaths. The latter has been found to be similar in mice treated with mutagenic agents and their control.¹⁶⁻¹⁸

The frequency of fertile matings in both control and treated groups seems not to be affected, particularly in the latter. Treatment of female mice of the same strain with the same dose of alcohol but for a longer period did not affect their fecundity (F.B., R.S.B. and M.E. Wallace, unpublished results). Prolonged treatments with larger doses were, however, reported to have some effect.¹¹

There is a close similarity between the average litter sizes of the control and the treated groups, with the exception of litters produced from matings that took place 14-17 d after treatment (Fig. 1). The difference in litter size of that group and the control is significantly different ($t=3.15$, $P<0.01$). The estimated dominant lethal mutation index is 38.3. The results suggest a considerable loss during prenatal life which could be, in large measure, the result of the induction of dominant lethals by alcohol. The results also suggest that different stages of germ cell maturation respond differently.

Although the matings were established at specific times, the entire period necessary to discern the precise pattern of differential response through spermatogenesis was not covered. A similar effect of alcohol on prenatal mortality has been reported with guinea pigs¹⁴, mice⁶ and rats¹².

A male that mated 10 d after cessation of treatment sired one young with abnormal bulgings on the head. The mouse was underweight for its age and died a few days after birth. All of its sibs were normal. The mother of the deformed mouse mated with the same treated father produced three more litters, none revealing similar or other types of abnormalities. It would be premature to conclude that this abnormality was due to alcohol treatment of the father.

Various abnormalities have been reported among progeny of animals treated with alcohol but in no case was there evidence that the alcohol caused any genetic changes.^{7,13,19}

Our second and third experiments were designed to obtain more specific information on the role of ethyl alcohol as a compound potentially able to induce dominant lethal mutation in the mouse. The two sets of data obtained from each experiment were analysed separately. The homogeneity of the data derived from the two experiments was

Fig. 3 Dominant lethal induction in male mice with ethyl alcohol. Effect on live implants. Symbols as in Fig. 2.

also tested and no statistical differences were found. This justified pooling the results of these two experiments presented in Table 2. The number of eggs shed, as represented by the number of corpora lutea at mid-term pregnancy, was not significantly different in the control and treated groups. Similarly, there was no significant difference in the number of total implants between control and treated groups.

The most striking observation is the significant (two to fourfold) increase in the number of dead implants in females mated 4-13 d after treatment of males with alcohol.

*Dominant lethal mutation index

$$= \left[1 - \frac{\text{Live implants of experimental group per female}}{\text{Live implants of control group per female}} \right] \times 100$$

†Statistically significant from the control values, $P < 0.01$

This considerable increase in post-implantation death is associated with a proportional decrease in the number of live embryos. These differences between the treated and control groups were statistically significant.

The dominant lethal mutation index was calculated using the formula given in Table 2. The values were based on comparison of the experimental groups of a specific mating interval and their concurrent control group. The estimated dominant lethal mutation index increased for matings between days 1 and 13 in the 40% group, reaching a peak during days 9 to 13. For groups treated with 60% alcohol, the increase in dominant lethal mutation index was rapid and abrupt with much higher frequencies at the mating intervals of 4-8 and 9-13 d. These frequencies (57.4 and 67.3) are higher than for groups treated with 40% alcohol (30.6 and 46.3) at the same mating intervals, which suggest in turn a positive dose response relationship. These results show that ethyl alcohol in the doses used induced dominant lethal mutations in several different spermatogenic stages, namely epididymal spermatozoa and late spermatids. The efficiency of induction is, however, more pronounced in the late spermatid stage.

Although the results derived from both experiments, the one based on litter size and the other on uterine contents, point to differences in the most sensitive stages of spermatogenesis both tests reveal the mutagenic nature of ethyl alcohol.

Dominant lethal mutations have been regarded as imposing no genetic hazards on man since they merely result in abortions. Whether ethyl alcohol could produce a wider range of genetic effects beside dominant lethals, needs further investigation. A pilot study on heavy drinking males indicates a significantly higher correlation between the incidence of birth defects and the drinking behaviour of the fathers (F.M.B., S. Beaton and R. Trudell, unpublished). Association between maternal alcoholism and aberrant morphogenesis in the offspring has also been described recently²⁴.

Evidence for postmeiotic effect of *t* factors causing segregation distortion in mouse

THE *t* complex of the mouse consists of a large series of genetic factors often characterised by embryonic lethality of the homozygotes, reduced male fertility of viable homozygotes, suppression of recombination over a relatively long chromosomal segment and relatively frequent occurrence in natural mouse populations. Most *t* factors also possess a component which interacts with the *Brachyury* (*T*) gene and causes complete absence of the tail in *T/t* heterozygotes. One of the most fascinating but least explored characteristics of the *t* factors is their effect on genetic segregation. A male mouse carrying a

Although this segregation distortion has been known for almost half a century, it has not been satisfactorily explained. It has been suggested that the distortion may be due to abnormal meiotic divisions (meiotic drive¹). More specifically, it may be due to a process in which homologous chromosomes distribute themselves unequally during metaphase I of male meiosis with the result that the spermatocytes receive one chromosome of a given pair more frequently than the other. Here we present evidence that in a *t/+* male, the *t* and the *+* bearing chromosomes are distributed during metaphase I in a 1:1 ratio, implying that the actual distortion must occur after metaphase I, most likely postmeiotically.

The evidence for the meiotic effect of *t* factors was obtained by cytogenetical means, using a strain of mice recently produced in this laboratory and carrying Robertsonian translocation *T(16,17)7Bn*, abbreviated *T7* (ref. 2). The strain was derived by repeated backcrossing of hybrids between the house mouse (*Mus musculus*) and the tobacco mouse (*M. poschiavinus*) to the inbred strain C57BL/10, and selection for chromosome 17 carrying the *t* complex. During the selection, six of the seven metacentrics present in the tobacco mouse were eliminated and only the one composed in part of chromosome 17 was maintained. The *T7* translocation is easily identifiable both at mitosis (as a single or double metacentric among 39 or 38 telocentrics, depending on the zygosity of the carrier) and meiosis (as a quadrivalent at metaphase I and a metacentric chromosome at metaphase II).

The rationale for the present experiment was as follows. If the segregation distortion is caused by meiotic drive during metaphase I, at metaphase II a *T7+/+t* male should show a preponderance of meiotic figures lacking the metacentric marker, if, on the other hand, the distribution of homologous chromosomes at metaphase I is normal, a 1:1 ratio of figures with and without the metacentric can be expected at metaphase II.

The prerequisite of such an experiment is that the *T7* translocation itself does not greatly disturb the segregation of the homologues at meiosis. For this reason, males carrying the *T7* marker but not the *t* factor were also tested.

** Observed frequency of progeny with *T7* from the mating of *T7*+/+*t* × +/+/+ or +/+/+*T* was compared to observed frequency of progeny from the mating +/+/+ × +/+/+ or +/+/+*T* (see column 12)

†† Number of progeny without *t*/total number of progeny. Progeny arose from matings of +/+/+*t* or +/+/+*t* to +/+/+ mice. Segregation of + chromosome was detected by H-2 typing.

‡‡ % progeny without *t* from matings in the absence of *T7*

§§ As B10.A lacks the metacentric chromosome, the four spreads scored as 1M must be reading errors. Two telocentric chromosomes which happen to be positioned in the spreads close to each other with their centromeres almost in contact and their arms pointing in opposite directions resemble and are confused with a metacentric chromosome. Such a reading error, however, is so small that it does not influence the conclusions drawn from the data.

In the experiment, $T7+/T7+$ females were mated to $+t/+T$ males and two types of progeny were produced $T7+/+t$ (normal tail) and $T7+/+T$ (short tail). Both the normal tail and the short males were further mated to $+/+/+$ or $+/+/+T$ females, the progeny of these matings were killed, mitotic chromosome preparations were prepared from bone marrow³ and the segregation of the $T7$ chromosome was determined. This progeny test provided the necessary control for demonstrating that the t factor distorted segregation whereas the $T7$ translocation did not. If this were the case, one would expect the progeny of the $T7+/+T \times +/+/+$ mating to segregate in a 1:1 ratio of mice with and without the metacentric, and the progeny of the $T7+/+t \times +/+/+$ mating to have preponderance of mice without the metacentric. After a sufficient number of progeny were obtained from the $T7+/+T$ and $T7+/+t$ males, the animals were killed, meiotic chromosome preparations were made from their testes⁴, and the metaphase II spreads evaluated for the presence or absence of the metacentric chromosome. Twenty to twenty-five slides were made from each male and only metaphase II spreads of 19 telocentrics and one metacentric, or 20 telocentrics were counted. Four different t factors were tested t^6 , t^{12} , t^{w2} , and t^{w5} .

Although there was a considerable male-to-male variation in the individual experiments (Table 1), the overall results with the different t factors were comparable (Table 2). In the meiotic test (Table 2), the observed frequency of 1M spreads (that is metaphase II spreads with one metacentric chromosome) in $T7+/+$ mice was not significantly different from the observed frequency of 1M spreads in $T7+/+t$ mice. When the observed frequency of 1M spreads in $T7+/+t$ mice, however, was compared to the expected frequency (50%), significant difference was found for some t factors (t^6 and t^{w5}). The departure from the expected value was most likely caused by the presence of the metacentric chromosome. (The frequency of 1M spreads in $T7+/+$ animals was lower than the expected 50% value, but for the number of animals used, the difference was not statistically significant.)

In the progeny test (Table 2), two t factors (t^{w2} and t^{w5}) were transmitted in almost exactly the same ratios in $T7+/+t \times +/+/+$ matings as in $+T/+t \times +/+/+$ or $+/+/+t \times +/+/+$ matings. The other two factors tested (t^6 and t^{12}), on the other hand, were transmitted in significantly lower ratios in $T7+/+t \times +/+/+$ matings than in $+T/+t \times +/+/+$ or $+/+/+t \times +/+/+$ matings. This latter observation suggests that $T7$ interacts with t factors postmeiotically, resulting in an increased transmission ratio of t . This interaction, however, can be detected only with t factors that, in the absence of $T7$, have low (t^6) or moderate (t^{12}) transmission ratios. The nature of the interaction is not known.

We conclude that two types of segregation distortion operate in the experiments we describe, one a very minor type occurring during the first meiotic division and another which has a very strong effect postmeiotically. The meiotic distortion can most likely be attributed to the presence of the $T7$ translocation, whereas the strong distortion is caused by the t factors and it may be enhanced by the $T7$ chromosome. Thus, the distortion resulting from t factors does not occur in metaphase I as a result of a structurally abnormal chromosome but rather postmeiotically. This conclusion is in agreement with the data of the effect of late mating^{5,7}, which shows a normalisation of the transmission ratios as a result of the shorter period of time between insemination and fertilisation. Further evidence for the postmeiotic effect of t factors is provided by recent work⁸ in which epididymal sperm were incubated *in vitro* and the number of surviving sperm were estimated at intervals by a cytotoxic test using antisera directed against a specific t factor. They demonstrated that the number of t bearing sperm increases with time as the number of $+$ sperm decreases.

The data we present, however, do not rule out the possibility of a biochemical activity related to the t factors that may occur before or early in meiosis but have a postmeiotic effect as

has been suggested by Erickson⁷.

Factor which affects the mode of genetic recombination in *E. coli*

THE normal recombination process in *Escherichia coli* requires a pathway involving a functional *recB* and *recC* gene product (henceforth designated the RecBC pathway)¹. The *recB* and *recC* genes map as closely linked cistrons near *thy* on the *E. coli* chromosome map (54 min)^{2,3}. ATP-dependent DNase (*recBC* DNase) has been identified as the product encoded by these genes⁴⁻⁶. Another gene essential for recombination proficiency, *recA*⁷, is located between *cysC* and *pheA* (51 min)⁸. Genetic transformation studies⁹⁻¹² showed that the most efficiently transformable *E. coli* strain (genotype *recB⁻ recC⁻ sbcB⁻*) lacks the DNase but retains recombination proficiency because of the *sbcB⁻* allele which acts as an indirect suppressor of the *recB⁻ recC⁻* mutations¹³. This strain uses a recombination pathway (designated as the RecF pathway)¹ which does not involve the ATP-dependent DNase but consists of products of several recombination genes¹³. Restoration of the ATP-dependent DNase to this strain by introduction of the *recB⁺ recC⁺* alleles reduced the transformation frequency by a factor of approximately five⁹. *In vitro* studies demonstrated that this DNase degrades linear DNA molecules extensively, while it has no effect on circular DNA⁴. The adverse effect of the DNase on transformation may therefore be due to destruction of linear donor DNA molecules before they reach the recombination machinery. These results raise the possibility that in normal cells the DNase affects the mode of recombination by selecting or destroying DNA molecules of a particular structure.

The transfer of genetic material can result in the formation of two possible types of recombinant clones: (a) substitution type resulting from replacement of recipient genetic material by a homologous segment of donor material, and (b) addition type

resulting from addition of the donor genetic material to the recipient chromosome. We describe here transduction and transformation experiments designed to examine the effect of the *recBC*-specified DNase on the two possible types of recombination. Similar experiments using λ *gal bio* were reported recently by Wackernagel and Radding¹⁴.

The genetic backgrounds of the *E. coli* K12 strains used in our study have been described¹⁰. M0639 is a tryptophan-requiring derivative (*trpB9579*)¹⁵ of JC7623 (*recB21 recC22 sbcB15*)¹⁶. Strains M0649 (*recB⁺ recC⁺ sbcB15*) and M0650 (*recB⁺ recC⁺ sbcB⁺*) were constructed from strain M0639 by conjugation with Hfr KL16.

We studied specialised transduction and transformation with ϕ 80pt and λ pt phages and their DNA¹⁷⁻²⁰. The ϕ 80pt and λ pt we used both lack the *int* and *red* genes which are replaced by part or all of the *trp* operon of *E. coli*. Two classes of Trp⁺ recombinants are generally observed in a single transduction (or transformation) experiment. One class of Trp⁺ recombinants consists of those lysogenised by donor phage by a mechanism similar to that of specialised transduction. Oka *et al.*²⁰ demonstrated that the entire ϕ 80pt genome integrates exclusively at *trp* operon of *E. coli* undergoing addition type recombination by the mechanism proposed by Campbell²¹. The other Trp⁺ class

between 10% and 20% (13.5% for ϕ 80pt, 17.0% for λ pt) of Trp⁺ recombinants were ϕ 80pt or λ pt lysogens, suggesting that these are the products of addition type of recombination. The rest (86.5% for ϕ 80pt, 83.0% for λ pt) were not lysogenic and therefore the products of substitution type of recombination. Second, in strain M0639 (recombination pathway RecF, no *recBC*-encoded DNase) the proportion of Trp⁺ recombinants which are ϕ 80pt or λ pt lysogens is drastically reduced to less than 1% of the total Trp⁺ recombinants so that almost all Trp⁺ recombinants result from substitution type of recombination. Third, in strain (M0649) (*recBC*-specified DNase present plus a functional RecF pathway) the proportion of the Trp⁺ recombinants harbouring ϕ 80pt or λ pt was the same level as that of M0650.

These results demonstrate that the presence of *recBC*-encoded DNase in the cells affects the fate of donor DNA and changes the proportion of two types of recombinants. Two possibilities can be considered to explain these results. First, the recombination process of the RecF pathway (*recB⁻ recC⁻ sbcB⁻*) results primarily in the substitution type of recombination, whereas the RecBC pathway (*recB⁺ recC⁺ sbcB⁺*) catalyses substantial amounts of both types (substitution and addition) of recombination. Second, the increase in the proportion of the

Table 1 Transduction of the *trpB* gene by ϕ 80pt and λ pt

Donor	Recipient strain	Genotype	Frequency of Trp ⁺ transductants ($\times 10^{-3}$)	Fraction of Trp ⁺ transductants harbouring the donor phage
ϕ 80pt	M0639	<i>recB⁻ recC⁻ sbcB⁻</i>	1.50	1/149 (0.7%)
	M0649	<i>recB⁺ recC⁺ sbcB⁻</i>	0.37	15/150 (10.0%)
	M0650	<i>recB⁺ recC⁺ sbcB⁺</i>	0.31	21/155 (13.5%)
λ pt60-3	M0639	<i>recB⁻ recC⁻ sbcB⁻</i>	5.40	1/155 (0.6%)
	M0649	<i>recB⁺ recC⁺ sbcB⁻</i>	1.80	17/155 (11.0%)
	M0650	<i>recB⁺ recC⁺ sbcB⁺</i>	0.56	27/155 (17.0%)

ϕ 80pt transduction was performed according to Oka *et al.*²⁰. λ pt transduction was performed as follows: overnight Luria broth cultures of the recipients were suspended in the same volume of 10 mM MgSO₄ and aerated for 15 min. The λ pt60-3 was added at a multiplicity of infection of 0.1 and the incubation was continued at 37°C for 20 min. The transduction mixtures for both ϕ 80pt and λ pt60-3 were appropriately diluted, plated on selection plates for Trp⁺ recombinants and incubated at 37°C for 48 h. The Trp⁺ transductants were purified by two single-colony isolations on Difco Bacto penassay agar plates before testing for phage-specific characteristics. More than 99% of the original Trp⁺ transductants remained Trp⁺ after the purification steps. The presence of the phage genome in the Trp⁺ recombinants was demonstrated by both the ability to produce the phages and immunity to clear-plaque mutants of the phages. For testing phage production the purified colonies were spotted on Penassay plates, irradiated with ultraviolet light and replicated on a plate having an overlay seeded with the indicator strain MRP1. A clear zone of lysis proximal to the spot was taken to indicate phage production. The test for immunity was performed by cross-streaking the Trp⁺ recombinants against ϕ 80c or λ c126. All the Trp⁺ recombinants immune to the clear plaque phages were induced by ultraviolet irradiation to produce phage whereas all sensitive recombinants produced no phage.

represents the substitution type recombinants in which only the portion of donor DNA bearing the *trp⁺* genes is introduced into the recipient genome. Such recombinants should not acquire ϕ 80- or λ -specific characteristics. Therefore testing Trp⁺ recombinants for the absence or presence of the phage-specific characteristics (phage immunity and inducibility) is a convenient method for determining the nature of the recombination process undergone.

We have tested for these characteristics in the Trp⁺ recombinants obtained from three isogenic Rec⁺ (*trpB⁻*) recipient strains. One recipient (M0650, *trpB⁻ recB⁺ recC⁺ sbcB⁺*) possesses recombination pathway RecBC and is dependent on the intact *recBC* gene-encoded DNase. The second recipient (M0639, *trpB⁻ recB⁻ recC⁻ sbcB⁻*) possesses only the RecF recombination pathway which functions without an intact *recBC*-DNase. The third strain (M0649, *trpB⁻ recB⁺ recC⁺ sbcB⁻*) possesses the two recombination pathways¹³. Table 1 presents the results of transduction experiments involving these strains with ϕ 80pt (*trpA⁺B⁺C⁺*) and λ pt60-3 (*trpA⁺B⁺C⁺D⁺E⁺*) and can be summarised as follows. First, in the wild type (M0650) where the DNase (encoded by *recBC*) is functioning,

addition type recombinants observed in the recipient with the *recBC*-encoded DNase (*recB⁺ recC⁺ sbcB⁺*, *recB⁺ recC⁺ sbcB⁻*) may be the result of decreased availability of a particular type of donor DNA molecule due to its degradation by the DNase. (For example, DNA with either total or partial linear structure, which is sensitive to degradation by the DNase⁴, may be the substrate for the substitution type of recombination. Circular DNA which would survive may be the substrate for the addition type of recombination.) We believe the second possibility is the case for the following reasons. First, the reduction of transduction frequency (3–10-fold) was always observed in the recipient cells with the *recBC*-encoded DNase (Table 1). Second, the frequency of spontaneous segregation of Trp⁻ cells from Trp⁺ lysogens due to the loss of the ϕ 80 and λ were equal (1.5% to 2%) in three recipient cells regardless of the recombination pathway(s) they possessed.

A similar experiment with a specialised transformation system was performed with intact ϕ 80pt (*trpA⁺B⁺C⁺*) DNA as donor and with the same recipients as used for the transduction experiment (except for strain M0650 which is non-transformable). Among the total Trp⁺ transformants the proportion which was

Table 2 Transformation with $\phi 80pt$ DNA

Recipient	Genotype	Frequency of Trp ⁺ transformants ($\times 10^{-6}$)	Fraction of Trp ⁺ transformants harbouring $\phi 80pt$
M0639	<i>recB⁻ recC⁻ sbcB⁻</i>	7.1	8/150 (5.3%)
M0649	<i>recB⁺ recC⁺ sbcB⁻</i>	1.4	104/144 (72.3%)

Specialised transformation was performed as described by Oishi and Cosloy²² using intact $\phi 80pt$ (*trpA⁺B⁺C⁺*) DNA as donor at a concentration of $10 \mu g \text{ ml}^{-1}$. Tests for phage-specific characteristics of the Trp⁺ transformants are described in the legend of Table 1.

the result of lysogenisation by the $\phi 80pt$ (*trpA⁺B⁺C⁺*) genome was distinctly higher with recipient strain M0649 than with strain M0639 (Table 2). This result is essentially the same as we obtained with specialised transduction. With both recipients a much larger proportion of $\phi 80pt$ -bearing Trp⁺ recombinants was obtained after transformation than after transduction, apparently due to a reduced frequency of the substitution type of recombination in transformation. This suggests that DNA molecules which enter the cell as a result of injection by phage tend to interact with the cell's constituents differently from DNA molecules which enter from a pool of naked transforming DNA, perhaps because of differences in structure or in the mode of entry. This interpretation is supported by the report²⁴ that for certain phage the presence of *recBC* DNase in recipient cells reduces the efficiency of transfection, which involves introduction of intact purified phage DNA, while it has little effect on plaque-forming efficiency by infection with intact phage particles.

We thank S. Orenstein for technical assistance and J. Tamayo for preparing the manuscript. We also thank Dr P. Margolin for critical reading of the manuscript and discussions. Strain MRPI was obtained from Dr H. Endo²³. Phages $\phi 80pt$ (*trpA⁺B⁺C⁺*) and $\lambda pt60-3$ (*trpA⁺B⁺C⁺D⁺E⁺*) were provided by Drs H. Ozeki and F. Imamoto, respectively.

Host range of murine xenotropic virus: replication in avian cells

AN endogenous C-type virus with an unusual tropism has been isolated from New Zealand Black (NZB) and other mouse strains. Although it has the murine leukaemia virus (MLV) *gs-1* antigen and reverse transcriptase, it cannot be propagated in mouse cells. It is only infectious for cells foreign to the host species and has been termed xenotropic¹⁻³. In the course of host range studies, we have discovered that, in contrast to other mammalian C-type viruses, this murine xenotropic virus can cross class barriers and both infect and replicate efficiently in avian cells. In these studies, the NZB pseudotype murine sarcoma virus (MSV) (Table 1) was used as it provides a good marker (focus formation) for NZB virus infection and replication.

As illustrated in Table 1, the NZB pseudotype virus gave efficient focus formation in a variety of mammalian cells including human, rat, guinea pig, rabbit, cat, cow, American bear, lion and African water mongoose. Infection occurred also in deer, racoon, gazelle, and Rhesus monkey. In the latter two cell lines only virus replication but not focus formation was detected. Infected animal cell lines which did not demonstrate focus formation nor NZB pseudotype virus production were cocultivated with human cells and passed three times. Supernatants were then assayed again for xenotropic murine sarcoma virus. These human cell cultures were also cocultivated with NRK-Harvey cells to determine if any NZB C-type virus were present. In all cases, the absence of progeny virus production in the original cell culture was not reversed by these added measures.

The xenotropic pseudotype sarcoma virus showed neither focus formation nor replication in C/O chicken cells including those established from *chf*-negative embryos. On the other hand, foci and progeny sarcoma virus were detected in duck, pheasant and quail cells. The foci formed in duck cells differed morphologically from those produced by Rous sarcoma virus (RSV). The MSV focus was composed of elongated, piled up cells rather than the round cells principally seen in RSV foci (Fig. 1a and b). The progeny sarcoma virus maintained the host cell tropism of the parental NZB virus as well as the NZB type specific coat as determined by neutralisation testing using antiserum prepared against the NZB C-type virus^{2,3}. Duck cell cultures yielded the highest titres of progeny virus.

As replication of the NZB pseudotype sarcoma virus requires the presence of a non-focus forming 'helper' C-type virus^{4,6,7},

Fig 1 Focus of cell alteration induced in duck embryo cells, *a*, by the NZB pseudotype murine sarcoma virus (Note the elongated piled up fibroblast-like cells) ($\times 24$), *b*, by the Prague strain of Rous sarcoma virus (note the accumulation of primarily round cells) ($\times 24$)

xenotropic C-type virus must also be produced by these cells. Duck cells were infected directly with the C-type virus isolated from NZB cells and these cultures also yielded progeny NZB xenotropic virus. Duck cell cultures producing xenotropic MSV and/or MLV were superinfected by RSV (type C), and continuous cultures producing both types of viruses have been derived.

Xenotropic viruses isolated from NIH Swiss, C57L and C57BL mice share the same type specific coat as the NZB virus (refs 2 and 3 and P. Arnstein, J. A. L., L. S. Oshiro, P. Price, and E. Lennette, unpublished) and are also able to replicate in duck cells; these data indicate this ability to cross class distinctions is a general characteristic of the murine xenotropic virus(es).

The Harvey strain of murine sarcoma virus as well as Rauscher and AKR pseudotype sarcoma viruses were also tested for their ability to infect duck cells. No foci were detected and supernatants from the cultures did not yield any focus-forming virus nor any MLV as determined by the XC plaque assay⁸. The Kirsten strain of MSV (K1-MSV) has been reported to have a wide host range including human cells⁹⁻¹², and we have been able to transform duck cells with an isolate obtained from a continuous line of rat cells chronically infected with K1-MSV. Infection of human cells, however, has not been possible with all preparations of K1-MSV (J. A. L., unpublished, and S. Panem and W. H. Kirsten, unpublished). K1-MSV in some laboratories seems to lose its tropism for mouse cells after passage through heterologous hosts (ref 11 and 12 and V. Klement, personal communication). As suggested previously², it seems most likely, that those preparations of Kirsten MSV contain significant amounts of xenotropic virus and its pseudotype sarcoma virus and these viruses are responsible for the wide host range observed. Neutralisation of the progeny virus from these cultures with antiserum against xenotropic virus is needed to evaluate this possibility. Recently we learned that the isolate we received from Klement has been neutralised by antiserum to xenotropic virus and not antiserum to the parental Kirsten virus (V. Klement, personal communication). This result

suggests that any MLV with a wide host range is most likely from the xenotropic MLV subgroup.

The variability in extent of focus formation and degree of progeny production by the xenotropic pseudotype sarcoma virus indicates that cells differ in their sensitivity for infection by the virus (input response) and their ability to propagate the virus after infection (output response) (Table 1). For example, although the same number of foci can be induced by xenotropic pseudotype sarcoma virus in human and rat cells with approximately the same multiplicity of infection, human cell cultures yield ten times more progeny virus (Table 2) than the rat cell cultures. As MSV replication depends on the helper C-type

Table 1 Host range of xenotropic NZB-MLV

	FF titre*	Progeny production†

Ring-necked pheasant embryo	30	03
Quail	+	03
Chicken embryo (C/O)	—	—

Fertilised duck (Pekin) eggs and lymphomatous-free white Longhorn chicken eggs (C/O) were obtained from Kimberlin Farms (Freemont, California) and used at 10–12 d of age for preparation of primary embryo cultures. Other avian cells were provided by Dr Don Fugita (San Francisco). Cells from the mammalian species were provided by Dr W. Nelson-Rees (Naval Biomedical Laboratories, Oakland). All cultures were maintained and passed according to standard procedures¹⁻⁴.

*The stock of NZB pseudotype sarcoma virus used was made by cocultivating non-virus producing MSV-transformed rat cells, the NRK-Harvey cell line, with NZB embryo cells²⁻³. This virus preparation was adsorbed undiluted for 30 min (37°C) on to the cell monolayers pretreated with diethylaminoethyl dextran⁵. Cell cultures were read for focus formation (FF) on day 7 and 9. The sensitivity of the cell line is expressed by the titre of xenotropic pseudotype virus (\log_{10}) obtained: +, Distinct foci could not be detected; —, no foci detected.

†Nine-day supernatants from cell cultures receiving 10^4 focus-forming units of pseudotype virus were assayed for progeny virus on human foreskin cells by standard techniques¹⁻⁴. The titre is expressed as \log_{10} . NT, Not tested; —, no progeny virus detected.

virus, these observations suggest that successful infection by xenotropic viruses involves at least two mechanisms, first, at the cell surface before penetration (for example, the receptor level), and second, intracellular after virus penetration. The former depends on the viral envelope coat, the latter on the viral genome. An intracellular block has been proposed to explain the reduced ability of murine N and B tropic viruses to propagate in certain mouse cells¹³. A similar type of block probably limits the replication of xenotropic virus in rat cells,

and other animal cells in which only focus formation is efficient (Table 1) Preliminary results in our laboratory suggest a block at the receptor level prevents xenotropic virus infection of hamster cells, and a block in both mechanisms is responsible for the resistance of mouse cells to the murine xenotropic virus (J A L, unpublished)

Table 2 Comparison of progeny yield after infection by NZB pseudotype sarcoma virus

Cells*	Foci†	Progeny yield‡
NRK	150	8

*Cells were inoculated at approximately the same multiplicity of infection

†Numbers represent the average number of foci in duplicate Petri dishes

‡Seven day supernatants from the cultures were assayed on human foreskin cells The average number of foci in duplicate plates is given

The growth of murine xenotropic virus in duck cells represents the first example of a C-type virus from one animal class replicating efficiently in cells from another animal class Svoboda and Klement reported tumours induced by RSV from which trace amounts of infectious RSV (ref 14) could be recovered Recently, the ability of the Schmidt-Ruppin strain of RSV to infect and replicate in kangaroo-rat cells¹⁵ has been described, but the efficiency of infection and replication by this RSV was much less than that of murine xenotropic virus in avian cells Moreover, after long term culture, the transformed marsupial lines tended to lose their capacity to produce virus¹⁵ On the other hand, duck cells, transformed by the NZB pseudotype virus have increased their virus production with passage and have yielded 10^5 – 10^6 focus-forming particles per ml as measured in either human, rat or duck cells

The xenotropic MSV can be used as a marker for molecular studies of cells producing both avian and murine C-type viruses Moreover, the sensitivity of certain avian cells to these murine C-type viruses provides another *in vivo* approach for studying xenotropic viruses and their possible role in normal development, evolution, autoimmunity and/or malignancy

Ki-MSV was provided by Dr V Klement I thank Ms Judy Joyner for technical assistance This work was supported by grants from the National Cancer Institute and the Jane Coffin Childs Memorial Fund for Medical Research

Delayed tumour appearance and absence of regression in nude mice infected with murine sarcoma virus

THE murine sarcoma virus (MSV) rapidly induces local tumours in mice^{1,2} The subsequent regression of such tumours in adult mice has been shown to be immunological in nature^{1,2} Young animals^{1,2} as well as animals immunosuppressed by X irradiation³, cortisol⁴, cyclophosphamide⁵, antilymphocyte serum⁶ or thymectomy^{2,7} have increased frequency of progressively growing tumours The immunological nature of these phenomena was also demonstrated by the transfer of resistance to tumour growth with cells³ or serum^{2,5,8} from animals that had regressing tumours The *in vitro* testing of lymphoid cells from mice with regressing tumours has indicated that both thymus-dependent (T)⁹ and non-T lymphocytes¹⁰ are generated as effector cells in this system

In the work reported here, the capacity to induce tumours and to produce spontaneous regressions of the developing tumours after MSV infection in adult *nu/nu* (nude-athymic) and *nu/+* mice (normal heterozygotes) was studied Nude mice have an abnormal development of the thymus and thymus-dependent systems and show a profound deficit of immune functions, especially of the thymus-dependent type¹¹

Nude mice partially inbred in a CBA/H background (5th to 6th backcross generation) and in BALB/c background (8th backcross, 2nd intercross generation) were used, as well as CBA/H or BALB/c mice (For details of origin of these strains and animal care see ref 12) All animals were free of lactic dehydrogenase (LDH)-elevating virus and had normal LDH serum values¹³, and all were injected intramuscularly at 50 d of age with 0.1 ml of Moloney strain MSV(M-MSV) In some experiments the *nu/nu* mice were treated with a thymus graft implanted intraperitoneally at 30 d of age (derived from 16–17-d-old CBA/H embryos or from BALB/c newborn donors) or with a thymus graft from CBA/HT6T6 origin enclosed in a diffusion chamber prepared with filters of a mean pore size of 0.10 μ m as described before¹⁴ Some experimental *nu/nu* mice were grafted at 30 d old with allogeneic C57BL/6 skin and these animals retained the grafted skin throughout the experiment All animals were observed for 50 d after M-MSV injection

Table 1 shows the results of such experiments M-MSV induced 100% local tumours in every experimental group, however, differences in the mean latent periods for local tumour development were observed While in the *nu/+*, CBA/H or BALB/c controls (experimental groups 1, 6, 7 and 12) the mean latent period ranged from 5.5 to 7.0 d, the latent periods for tumour development in the *nu/nu* groups (groups 2 and 8) were 19.1 and 16.8 respectively, which are significantly prolonged compared with any of the control groups The same prolonged latent periods for tumour development were observed in the two groups of *nu/nu* mice grafted with allogeneic skin to monitor immune incompetence (groups 3 and 9) Conversely, the *nu/nu* mice grafted with a free thymus graft (groups 4 and 10) behaved as the normal *nu/+* and had short latent periods for tumour development (7.1 and 6.9 d respectively) On the other hand, thymuses enclosed in a diffusion chamber were incapable of shortening the long latent period for tumour development in the *nu/nu* (group 5) A small additional group (group 11) of *nu/nu*-BALB mice injected intraperitoneally at 30 d of age with 100×10^6 cells from 60-d-old *nu/+* BALB thymuses showed

only a slight prolongation of the latent period for tumour appearance when compared with controls

Within the groups of *nu/+* mice, immune competence of some animals (16 in group 1 and 7 in group 7) was tested with grafts of C57BL/6 allogeneic skin at 30 d of age. Skin graft rejection within 12 d of grafting was observed in every instance (9.9 and 9.2 days respectively) and since such groups did not differ from the non-grafted animals in behaviour towards M-MSV infection, they were not considered as separate groups in Table 1.

Table 1 also shows the total incapacity of *nu/nu* mice to produce regressions of the developing tumours (groups 2, 3, 8 and 9). Conversely, the immunologically normal controls (groups 1, 6, 7 and 12) produced regressions in almost every instance within 10–12 d after tumour appearance. The thymus

suggesting that the target cell for the humoral activity of the thymus in the peripheral lymphoid tissues is a post-thymic cell which is absent in the *nu/nu* mice.¹⁴

The delay in tumour appearance in *nu/nu* may be explained by the inability of these mice to develop the early atypical granuloma which is a common feature of the M-MSV-induced tumours in normal mice.²³ Analysis of the cellular composition of the tumours appearing in an additional group of 5 *nu/nu* and 4 *nu/+* (on BALB/c background) supported this interpretation. The cellular composition, studied 7 d after tumour appearance (cells dispersed by 30 min incubation in 0.25% pronase) was 25–30% tumour cells in the *nu/+* versus 43–66% in the *nu/nu*, the remaining cells being lymphocytes, polymorphs and macrophages. The proportion of macrophages within the tumours (determined by ability to ingest latex particles) was

Table 1 Tumour incidence and regression in *nu/nu*, *nu/+*, CBA/H and BALB/c mice after injection of M-MSV

Experimental groups	No. with tumours per total injected	Mean latent period for tumour appearance (d ± s.d.)	No. of tumours regressing	Mean regression time (d ± s.d.)
(1) <i>nu/+</i> (CBA)	39/39	6.5 ± 1.9	39 (100%)	10.8 ± 2.1
(2) <i>nu/nu</i> (CBA)	21/21	19.1 ± 3.7	0	—
(3) <i>nu/nu</i> (CBA-Sk)	10/10	19.6 ± 2.5	0	—

(5) <i>nu/nu</i> (CBA-TDC)	10/10	16.9 ± 2.7	0	—
(6) CBA/H	20/20	7.0 ± 1.6	19 (95%)	12.1 ± 1.9
(7) <i>nu/+</i> (BALB)	16/16	5.5 ± 1.2	14 (87%)	10.2 ± 1.8
(8) <i>nu/nu</i> (BALB)	12/12	16.8 ± 2.4	0	—
(9) <i>nu/nu</i> (BALB/Sk)	7/7	17.2 ± 2.1	0	—
(10) <i>nu/nu</i> (BALB-TG)	12/12	6.9 ± 1.5	10 (83%)	10.6 ± 1.5
(11) <i>nu/nu</i> (BALB-Thy)	6/6	10.0 ± 2.1	2 (33%)	13.5 ± (12–15)*
(12) BALB/c	20/20	5.8 ± 1.2	17 (85%)	10.6 ± 1.6

All mice were injected at 50 d of age intramuscularly in the left thigh with 0.1 ml of 1:2 diluted M-MSV containing $5-8 \times 10^8$ focus forming units per ml when tested in secondary BALB/c mouse embryo cell cultures. The original stock of M-MSV was obtained from Electro-Nucleonics Laboratories, Bethesda as M-MSV-infected BALB-3T3 cells. All virus used in the present experiments was prepared as in ref. 15 as 1 g ml⁻¹ equivalents from M-MSV tumours produced in BALB/c mice, divided into aliquots and stored at -75°C. The virus used was apparently free of LDH-elevating virus, since infected mice showed normal LDH serum levels, measured as in ref. 13. 'Tumours' indicates development of nodules at the injection site. CBA indicates those *nu/nu* and *nu/+* mice which are in CBA/H background. BALB indicates those *nu/nu* and *nu/+* which are in BALB/c background. Sk indicates allogeneic C57BL/6 skin grafts. TG indicates a thymus graft implanted intraperitoneally (i.p.). TDC indicates a thymus within a diffusion chamber implanted i.p. Thy indicates the i.p. injection of 100×10^6 thymocytes from adult *nu/+* BALB mice. All these procedures were performed at 30 d of age. All animals were observed for 50 d after M-MSV injection. Mean regression times were calculated excluding those animals that did not show regression. Asterisk indicates actual regression times. By Mann-Whitney non-parametric tests¹⁶ the differences in regression times between non-overlapping populations are significant.

dependency of these regressions was demonstrated by the effect of thymus grafting in the *nu/nu* mice (groups 4 and 10) in which regression was observed in 92 and 83% respectively of the animals. Conversely, thymuses enclosed in a diffusion chamber were ineffective in supporting regression of the developing tumours (group 5). The small group of *nu/nu* BALB injected with dispersed syngeneic thymocytes (group 11) showed regressions in 2 of 6 instances (33%).

These studies show that the capacity to produce regression of M-MSV-induced tumours has a strict thymus dependency. The exact immunological mechanism by which these regressions are produced is still undefined. Both antibodies^{2,5,8,17} and cells³ can transfer immunity *in vivo* and both T^{9,18,19} and non-T cells^{10,19} as well as normal lymphocytes in the presence of immune sera²⁰ or immune serum and complement²¹ behave as effector mechanisms in inhibition of tumour growth or cell kill *in vitro*. Whatever the mechanism(s), the thymus is required for the generation of such effector products, whether cells or antibodies. Additional factors may, however, be important since considerable differences in tumour growth and regression were observed between different stocks of M-MSV^{2,22}. The inability to restore the capacity to produce tumour regressions in *nu/nu* mice with thymus enclosed within a diffusion chamber, while free thymus grafts were effective, supports our results

30–41% in the *nu/+* and 17–26% in the *nu/nu*. The results in the *nu/+* mice are comparable with those observed by others in early M-MSV lesions²⁴. When these relative values were expressed as absolute number of cells, the differences increased, since the total number of cells per tumour was higher in the *nu/+* mice (mean values 2×10^8 for *nu/nu* and 6×10^8 for *nu/+* mice), however, variability of the cell yield per tumour precludes interpretation without further study. The present evidence can be interpreted as a consequence of impaired granuloma formation and/or the reduced rate of transformation or reduced rate of proliferation of the transformed cells in the nude mice. These differences in cellular composition were also observed in histological sections and are presently under study. This interpretation is also supported by the long latent period for tumour development observed in mice irradiated with 350 r and infected with low doses of M-MSV¹. The proportion of atypical granulomas compared with sarcomas defined histologically was, however, comparable between normal or thymectomised or irradiated mice²³.

The naturally occurring cytotoxic anti-tumour antibodies described in the serum of nude mice²⁵, may also play some role in our observations. These antibodies are complement-dependent and can lyse various tumour cell lines (including two M-MSV lines) and are not detected in *nu/+* mice at any age,

however, the incidence of such antibodies in the sera of individual mice from our colony, both in the BALB/c and CBA/H background, is relatively low, never above 30% of the animals tested at ages ranging from 50 to 120 d (my unpublished results). Of the 12 nudes (BALB/c) in group 8 (Table 1) that were pretyped for presence or absence of such antibodies, three had detectable titres when tested against EL4 cells and M-MSV transformed Swiss and BALB/c cell lines. The two animals with the longest latent period, 21 and 23 d respectively, had no detectable titres. All the *nu/+* tested (group 7, Table 1) had no detectable titres. It is apparent that additional work, especially correlations of *in vivo* and *in vitro* reactivity using this model may solve some of these quandaries. Alternative interpretations such as the possible stimulatory role of the incipient immune response on tumour growth²⁶ or the possible absence of T cells with suppressor activity in the nude mouse²⁷, cannot be excluded.

Doubling time (min)§			65	85	70	97	90	135

* Log phase cells were adjusted to approximately 5×10^4 colony forming units per ml in fresh growth medium, 2 ml of this dilution was added to tubes containing the given polyenes. Dimethyl sulphoxide was present to 1% in all samples including the blank control. After overnight incubation at 37° C, the turbidity was recorded.

† A single colony of the given strain was streaked out on plate containing the given polyenes, and the growth was checked after 24 h of incubation at 37° C. The nystatin ($4,530 \text{ U ml}^{-1}$) and the amphotericin B ($876 \mu\text{g ml}^{-1}$) were gifts from the Squibb Institute of Medical Research.

‡ Liebermann-Burchard reaction used. Total lipid extract of whole cells were used for assay. Preparations from both log and stationary phase cells gave identical results.

§ Growth was monitored turbidimetrically with a Klett-Summerson photoelectric colorimeter (green filter).

reviews

WHEN Maurice Clavelin's *Essay on the Origins and Formation of Classical Mechanics* first appeared in French in 1968, it was widely recognised as a work of much originality, and nothing published since that first appearance has made very serious inroads into his main conclusions. The *Essay* is a long and intensive study of "a transition from one conceptional framework to another, the replacement of one explanatory ideal with another and an unprecedented fusion of reason and reality", and M. Clavelin argues that to evaluate the scope of the revolution "we must try to view Galileo's work from within". He professes to make no systematic reconstruction of the intellectual and social context in which Galilean science evolved, and yet, overlooking these modest protestations, the reader will have no difficulty in extracting just such materials. The book begins with the Aristotelian doctrine of motion—the intrinsic analysis of local motion, the cosmological frame without which local motion (for Aristotle) was inconceivable, and the descriptive analysis of local motion (the classification of it, the evaluation of its magnitude, and resistive force). By emphasising the coherence of the Aristotelian theory, and the interrelations of the cosmos and local motion, M. Clavelin explains how—far from being the heap of inanities some popular histories would have us believe—it could be questioned and extensively qualified by great minds, without collapsing into a pile of rubble. And if that is important to an understanding of Galileo, then the traditions of the 14th century schools of Oxford and Paris was even more so.

In that connection, Galileo for long misled his commentators by lavishing praise on Archimedes at the expense of Aristotle. Of the fact that Galileo's technical language owed much to mediaeval precursors there is no doubt, but how extensive was his debt to them? Like them, Galileo at first tried to relate the increase in speed of a falling body to its spatial position rather than to time (After all, according to Aristotle, motion depended on position.) The mediaeval doctrines were an established part of the teaching he had at Pisa between 1583 and 1586. In his *Juvenilia* Galileo reveals himself as in many respects an Aristotelian, and his early *Treatise on the Latitude of Forms* includes many allusions to the Mertonians and Parisians. Simultaneously

Focusing on Galileo

J. D. North

The Natural Philosophy of Galileo: Essays of the Origins and Formation of Classical Mechanics By M. Clavelin. Pp. xiii+498 (MIT Press, Cambridge, Massachusetts, and London, 1974). \$25.00. *Two New Sciences* Including *Centers of Gravity and Force of Percussion* By Galileo Galilei. Table introduction and notes by Stillman Drake. Pp. xxxix+323 (The University of Wisconsin Press, Madison, Wisconsin, 1974). \$14.00 cloth, \$5.00 paper.

ously with these early writings, however, Galileo was reading Euclid, Archimedes (especially on hydrostatics), and Tartaglia (on projectiles). These works convinced him of the need to replace the textual criticism and qualitative dialectic of the philosophers with a direct and mathematical method. The first taste of the great power of the essentially geometrical method for the analysis of physical problems was evident in the early works *De motu* and *Mechanica*. For the greater *Dialogue and Discourses*, in which the method was exploited far more fully, the world had to wait some decades, and this because from 1602 until his death in 1642 Galileo found a need to link Copernicanism with the mathematical science of the motion of heavy bodies. Into this period, of course, came the telescopic discoveries which so distinguished the Galilean outlook. M. Clavelin reminds us how important was the cosmological component in thought about motion, before Newton's time. Galileo, for instance, was never to abandon the view "that circular motion alone had an actual and real power of indefinite self-conversation". Unlike his precursors, we are told, Galileo was able to treat local motion as a state rather than as a process, and Copernicanism indeed set Galileo the problem of justifying the idea of an orderly world in which motion, not rest, is the normal state of the Earth. His analysis of the Earth's diurnal motion (as in the Second Day of the *Dialogue*) led him to create some of the most significant of his mechanical concepts—such as the idea of an inertial system, the principle of the conservation of uniform motion, and the principle of the composition

of motions. M. Clavelin explains all that beautifully, and at length, steering a middle course between the positivism of Duhem and the Platonism of Koyré. He contrasts the contents of the *Dialogue* with the corresponding parts of the *Discourses*, and at the same time emphasises a "lack of cohesion" in Galileo's mechanical ideas which denied him the opportunity of discussing properly the planetary motions in mechanical terms, and which indeed made impossible the treatment of weight as a force.

Before Professor Drake's work, the last important English translation of the *Discourses* (1638) was prepared by Henry Crew and Alfonso de Salvio in 1914 under the title *Dialogues Concerning Two New Sciences*. Earlier English translations had been published in 1665 and 1730. In the introduction to Drake's new translation, reasons are given for thinking a new version desirable. The changes are not such as to strike the casual reader as very significant, but it is the very fact that they are spelt out at length which gives the new version its value. Take the (Italian) noun *mobile*, for instance, signifying a tangible and heavy moving object near the Earth's surface. This is now rendered by the English 'moveable', in contradistinction to the adjective 'movable'. Crew and De Salvio translated *mobile* to mean 'particle', to which objection is now made on the somewhat curious grounds that "the modern physical particle is essentially devoid of weight". As another example, Professor Drake dislikes the introduction of the mediaeval concept of "mean speed" into the statement of Galileo's basic first theorem on accelerated motion, in place of "one-half the final speed". Whatever the reader's feelings over these subtleties, it is undeniable that the new version must now replace the others. It includes original Galileo works which were published posthumously in the form of a dialogue on the force of percussion (intended for the 1638 edition, but not finished to Galileo's satisfaction), and Galileo's work on centres of gravity. Professor Drake, whose reputation as a Galileo scholar is well known, adds some useful notes, as well as a bibliography of the principal editions and translations of the *Two New Sciences*. The new version, like the original Leyden (Elzevirs) edition, is very attractively designed and printed, and not unduly expensive. □

Management of natural systems

Genetics of Forest Ecosystems By Klaus Stern and Laurence Roche Pp 330 (Chapman and Hall London, Springer Berlin and New York, 1974) £12 25

In his preface Roche states that forest ecosystems are a rich source of information on ecological genetics but that published evidence has not yet significantly penetrated the botanical literature. Little exception could be taken to the first part of that statement, and the book, itself a rich source of information, goes some way towards correcting the imbalance mentioned in the latter part. But according to the introductory remarks by Stern the book aims to be more than a catalogue of information on stable and transitory forest ecosystems. Stern assumes that forest ecologists and breeders have been more concerned than agronomists with the inner mechanisms of ecosystems and that only by knowing these mechanisms could the former group hope to improve the economics of forestry. Accepting that this is true and that ecologists and breeders significantly affect forestry practice, then discussion of the state of man's knowledge of these mechanisms, which form an important part of the book, is a valuable contribution to the intelligent management of the world's forest resources.

The main subjects—ecological niches, adaptations, genetic systems, adaptive strategies and forest ecosystems—are approached in a similar manner throughout. First, formal definitions are stated and discussed and that is followed by a consideration of mathematical concepts and their limitations and applicability. Finally, examples are given, mainly from the forest ecosystem, to illustrate and complement the previous discussions. The use of the concepts of systems theory, games strategy and cybernetics will provide difficult reading to the uninitiated. Such difficulties are compounded by the odd misprint, the occasional grammatical peculiarities, and a style of writing which may well be a consequence of translation from the original German.

In a book of this scope it is always possible to find something to criticise but I must say that I thought that the chapter on genetic systems of forest trees species placed undue emphasis on selfing, whereas the reader was referred elsewhere for information on other aspects. And there is much space devoted to Fowler's work on *Pinus resinosa* but his conclusions are reported erroneously in the text. On the other hand, there is much of which I approved, such as the discussion of the

tropical ecosystem, which emphasises and contrasts the ideas of Federov and Ashton.

The final chapter, contributed by Roche, is a review of man's effect on the ecosystem. It is proposed in the introduction that this chapter could well have been placed in a separate book. Had it been placed at the beginning of this book, however, its contents would have encouraged those whose activities affect the forest ecosystem to read the following chapters.

Ian R. Brown

Viral diseases

Slow Virus Diseases Edited by John Hotchin Pp xvii+372 (Karger AG Basel, London and New York, 1974) £19 80, \$49 75

THE title of this book is misleading for the text is concerned mainly with persistent viral infections. 'Slow' infections constitute only a small and unrepresentative group. Seventy pages describe the arena virus group of which LCM virus is the prototype. In contrast, the 'slow' virus diseases are described less adequately. Thirty pages outline reasons for viral persistence, and examples of diseases of man and animals in which persistent virus is considered important in pathogenesis are written about with varying clarity by 27 specialists. All in all, the book is a useful introduction to a developing but not well-defined area of medicine. John T. Stamp

Plants beneath the rising Sun

The Flora and Vegetation of Japan Edited by M. Numata Pp x+294 (Kodansha Tokyo, Elsevier Scientific London and New York, 1974) Dfl80, \$30 80

SINCE 1950, the Japanese have achieved an international reputation for the originality and importance of their contribution to quantitative studies in plant ecology. The analysis by Monsi and Saeki of the attenuation of solar radiation intercepted by herbaceous vegetation, the application by Hozumi of allometric methods to the estimation of growth of forest stands, and the studies by Kira and his associates of intraspecific competition are all examples of work which has attracted world-wide attention. Recognition of the significance of this work has been facilitated by publication in English and German. In contrast, most of the literature on the vegetation of Japan

has been published in Japanese so that it remains relatively inaccessible. Now a concise guide is available in English and it provides an excellent account of one of the most intensively studied and interesting vegetational regions of the world.

Modern Japan extends from the northern coast of Hokkaido (latitude 46° N) to the southernmost of the Ryukyu islands which is almost on the Tropic of Cancer, a distance of over 3,000 km along the great archipelago which stretches from Kamchatka and the Kuril Islands in the north to Formosa (Taiwan) and the Philippines in the south. During the climatic vicissitudes of the Pleistocene, the continuity of the archipelago seems to have allowed much of the Eocene flora to survive by oscillating from north to south and back. Consequently, the flora of Japan is extraordinarily rich, with almost 4,000 vascular plants, including many endemics and relict species of the Arcto-Tertiary flora, and a great wealth of woody species.

Small areas of sub-tropical vegetation occur on the Ryukyu islands but the original vegetation on the main islands ranges from warm temperate forests, comprising largely evergreen broad-leaved species in Kyushu, Shikoku and southern Honshu, to cool temperate forests, characterised by beech (*Fagus crenata*) and representatives of several familiar temperate genera such as *Acer* and *Prunus*, in northern Honshu. Subarctic coniferous forests of *Abies sachalinensis* and *Picea* spp. are present on the mountains of Honshu and descend to sea-level in Hokkaido. This latitudinal zonation is accentuated by the warm Tsushima and Kuro-shio currents which originate in the tropics and have a large influence on the climate of the southern islands but which fail to reach Hokkaido.

Much of the land which would naturally carry forest has been modified greatly and is now occupied by grassland or vegetation dominated by *Pteridium aquilinum*. There is a wide variety of coastal vegetation and extensive regions of subalpine and alpine vegetation, in which a majority of the genera are those important in Europe. The final section is devoted to an account of the vegetation of active volcanoes and includes some remarkable illustrations of recent lava flows and pumice deposits now covered by forests.

The book provides a clear and fascinating account of Japanese vegetation and of the many geographical and ecological problems presented by its complexity and its considerable modification by man. It is well written, well balanced in its presentation and has numerous illustrations which are uniformly of high quality. C. D. Pigott

nature

January 17, 1975

Should we leave it to the mystics?

THE French postal strike delayed until recently the arrival of the latest of one of UNESCO's more interesting periodicals, *Impact of Science on Society*. There are several journals attempting to fill the role of spanning the gaps between science, policymakers, educationalists and the public, and all of them, one suspects, suffer from the same problem: the scientist feels he should read them, but never quite finds time.

Impact (its long title sounds a little dull, its short one suggests it should be on the bookstalls along with *Probe*, *Thrust*, *Health* and . . . *Nature*) is always worth devoting time to, and this most recent issue, on the parasciences, is no exception. A dozen writers provide essays on subjects ranging from the design for a spaceship reported in the Book of the prophet Ezekiel to vision through the fingers. The whole is elegantly introduced through an essay (adapted from the *The Roots of Coincidence*) by Arthur Koestler.

One of the persistent complaints of those who work in fields outside orthodox science is that they cannot get scientists to take them seriously—although one must note that of 48 past presidents of the Society for Psychical Research, nine were Fellows of the Royal Society. And yet there are some, both scientists and parascientists, who believe that the two fields represent opposite sides of the coin and scientists should not be brought in to attempt to explain what is inexplicable in their terms (in much the same way that science and religion seem, on the whole, to have kept each other at a respectful arms-length). It is thus a matter of some interest to see what parascience says when given a highly respectable platform from which to speak to the establishment.

The result is somewhat disappointing. Part of this, no doubt, stems from the necessary variability produced in bringing together authors from many nations. But part of the disappointment is that, with the exception of Koestler, none of the proponents of the parasciences really gets down to the serious business of trying to persuade the reader that there is something in it.

Koestler is an exception because he can see the strange side of the modern physicist's perception of nature and he can play on it to create a certain malaise in the reader's mind. Time reversals, anti-matter, a hundred or more elementary particles—scientists can accept these, but still choke on the thought of extrasensory perception, let alone psychokinesis. It's a good though certainly not a clinching argument, but much of what follows in the journal demonstrates why it is that scientists are still sceptical. Practitioners either indulge in the production of wide-ranging samplers of superficial and inadequately reported observations, or plunge into extended deep speculation without so much as a glance at the reader to see if he

needs any convincing even to take the first step.

Yet for all this there are some good things, particularly where science and technology are allowed to do the explaining. Kirlian photography, the observation of corona discharges, is well dealt with by Rudolph Guzik, who makes it clear that a very complex (and in a sense unpredictable) phenomenon can be understood within the confines of 'normal science' provided that mystics, using words like 'life force' and 'psionic aura' do not enshroud the whole field in nonsenses and drive away those who could put it on a rational footing. One suspects that this is a paradigm for much of what exists in and beyond the fringe of science. There are many things which in the past were deemed not 'normal', that is not common-place experience. Among these could be included eclipses, earthquakes and mirages, and all of these have yielded to rational study. Nor is science reckoned to have failed because some of these phenomena are irregular and unpredictable as yet. Other 'not-normal' phenomena, being less easy to master scientifically and more susceptible to the attentions of quacks and tricksters, have now receded into a world of the half-light, and the scientist wishing to investigate has first to discern whether he is being taken for a ride by the practitioner. He may rather be taken for a ride by his own senses, and this indisputably is a subject worthy of research; a scientist may be able to satisfy himself that the practitioner is not consciously deceiving but be unqualified to spot his own perceptual errors. For a start he should be suspicious of any phenomena which require darkened rooms or his ability to absorb a wide variety of happenings and pronounce on the normality or otherwise of one of these—not necessarily the one he was concentrating on.

There may well remain, however, things worthy of our attention—a sort of dry residue. The parasciences may not yet have unearthed much for which there is a cast-iron case for scientific explanation, but there is ample material crying out for verification, and the lessons learnt over the last few years should have improved techniques and procedures for getting to the heart of the deception/reality question. Now, surely, is the time for scientists in large numbers to take a more practical interest in these obstinate issues. If we fail to do so, parascience will recede further into the mystic's world and will take with it much of the public's sympathy.

Investigation in the para-world is neither easy nor always agreeable. Public interest, however, demands, rightly or wrongly, that scientists come to grips with the propositions being made. And if scientists won't come in with rational attitudes and, where necessary, rational explanations, they can hardly be surprised if the forces of irrationalism take over. □

Any old Fe₂, Cu, Al, Pb, Zn, glass, paper. . . ?

The future availability and price of key raw materials, placed in doubt by the events of the past year, have emphasised the need to conserve by recycling. Attitudes in the UK are reflected in the following three articles. The first is by Christine Thomas, of Friends of the Earth.

IN modern times, industrial societies have been characterised by an attitude to the use of resources which earlier societies necessarily regarded as untenable. The difference in attitudes was born of a different appreciation of resource availability: in recent years industrialised regions have evolved a sophisticated system of resource-monopolisation and hence cost-control which enabled them for all practical purposes to regard raw materials as infinite or at least theirs for the taking.

This system and the attitudes which it bestowed are now breaking down for two reasons. First, there has emerged a greater maturity of view shared by many of the countries described alternatively as 'developing' or 'emergent', which have important raw material reserves. Second, the real resource scarcity predicted for certain commodities has begun to bite and has been reflected in the rising prices of raw materials.

It is therefore self-evident that the more efficient use of raw materials in 'developed' countries should become an important 'development' goal. Britain, a country more heavily dependent than most on the import of essential raw materials, can no longer afford to discard over 100 million tonnes of waste every year. Even if more efficient recycling systems and policies of re-use were instituted, Britain would still be dependent on raw material imports.

Recycling of industrial products is one option that can lead to a thrifter use of resources. By attempting to approximate to natural cycles, such as those for carbon and nitrogen, where no material is lost from the system, recycling can partially close the loop of industrial production. By doing so this decreases both the production of waste and the extraction of virgin raw materials associated with a given level of materials consumption.

Current practice though shows these loops to be far from closed. The table below illustrates the present use of reclaimed materials in Britain. The figures in the first column are deceiving as they include the use of 'new' scrap or manufacturers' scrap. More telling is the percentage of 'old' or 'post-consumer' scrap recovered.

Material	% (by weight) of total production accounted for by:	
	All scrap	Old scrap
Iron and steel	52	10
Copper	40	13
Aluminium	30	—
Zinc	25	—
Lead	65	—
Glass containers	22	3
Paper	43	15-30

Comparison between the energy requirements for a number of metals produced from secondary materials and from their ores show that for the former the energy needs are invariably smaller. Often dramatically so, as with aluminium where the energy costs of its production from bauxite are 30 times that for its production from scrap. Recycling paper also offers potential energy savings, as production of fibreboard from virgin pulp requires about twice the amount of energy compared with its production from waste paper.

The British Steel Corporation accrue considerable savings through their recycling efforts. They used 19 million tonnes of scrap steel last year, nearly half their raw material requirements and with a 30% saving in energy associated with processing scrap this resulted in almost 80,000 kWh (thermal) saved.

Since it would seem desirable on many accounts to maximise our recycling effort, why is current performance so low? Basically it is a question

of economics. In many cases it does not pay the individual firm to recycle, even though it would be of benefit to the country as a whole. A situation therefore arises in a free market, in which industry can externalise the social and environmental cost of production, creating a situation where virgin material use does not reflect its true cost to society. Thus recycling suffers unreasonably in competition with raw materials.

One controlling factor which is often overlooked and which is of great importance in deciding what is a desirable level of recycling is energy. In many cases recycling would not be justified where the energy costs of recovering a material far exceed that of initial production. Generally this is not the case, but mixing materials together, particularly in small proportions, makes it energy expensive to reverse the process and recover one material.

An additional constraint on the achievements of recycling is imposed by our attempts to continue growth in the production of consumer goods. In a 'growth' situation, reclaimed material arising from the previous year's production cannot by definition meet this year's demand. And in a situation of exponential growth the gap between the total supply of materials required to meet demand and that met by recycled products will continue to diverge.

The front rank of the scrap metal trade, where an infrastructure of merchants has been built up over many years to feed metals back to the smelters.
Picture by John Rigby.

John Newell reports on a recycling system which is being operated at a government laboratory.

THE automated pilot rubbish sorting line is now working at the Department of Industry's Warren Spring Laboratory. And most of the data concerning the total municipal and industrial waste produced by the county of Oxfordshire has now been assimilated in a project at the same laboratory which is intended to estimate how much of the raw materials needs of such a typical area could be met by a wasteplex, a single, central, all-purpose recycling centre. Great interest has already been shown in the Warren Spring Waste Materials Exchange, which will act as an information service providing regular quarterly bulletins, shopping lists of waste products which could be just what are needed as raw materials by someone else. Although the Warren Spring Laboratory is now spending at least four times as much as they were five years ago on recycling engineering, their resources are still limited when compared with the USA. The members of the team, which has been trying—and now succeeding it seems—to interest industry in new recycling technology developed at the laboratory, can be excused some irritation with accusations in the media that they are partly responsible for sluggish British

interest in moving away from tipping and towards recycling of solid and other wastes.

The sorting line now occupies about half a hangar-sized shed. It is fed by six tons at a time of raw rubbish from Stevenage dustcarts. The rubbish goes through a bag burster and then a rotating drum, which sorts it through three successive sieves with increasingly large holes. The various conveyors coming off this take their loads past magnets, low powered fans, a water bath to separate light from heavy constituents, and devices where rubbish is flung off high speed conveyors against angle plates, or drums rotating in the opposite direction, to make use of differences in the coefficients of friction and resilience.

Out of the other end, or rather ends, come several potentially valuable by-products. Three grades of reusable paper, two already pronounced as suitable for board making by commercial board mills, one suitable for high grade fuel; clean tin cans for remelting; vegetable matter for composting or conceivably for animal feed, coarse rags for floor covering materials and fine particle materials for soil conditioning.

Warren Spring has also developed means for separating glass to a very high degree of purity because, although there is little commercial future for recycled glass in high grade uses at

present, the position may change, and recent developments in glass fibre manufacture make it likely that this will soon become a large scale outlet for recycled glass.

The lowest grade, dirty, wet mixtures of plastic, paper and other organic unmentionables could at least provide heat, if distilled in a pyrolysis plant set up on a wasteplex site. Warren Spring finalised its designs for a pyrolysis plant earlier this year, after some years of research, and are now waiting for the go-ahead to build a commercial version for a local authority. It has also had fully developed for some time an ingenious fluidised-bed technique for separating different non-ferrous metals.

As a result of talks now in progress, Warren Spring hopes that a first rubbish recycling line, probably using not just a few elements but most or all of the different sorting techniques it has developed, will be built for a local authority somewhere in Britain within 12 months. There will probably be no need to scale up since the existing plant can cope with 50 tons every 24 hours—the equivalent of the rubbish output of a city of about 50,000 people.

Unlike rivals, the Warren Spring system keeps rubbish in large lumps as far along the line as possible. Shredding is a late stage. This prevents the transfer of dirt to paper and tin cans that are being squashed inwards into their contents, and generally makes sorting, especially of glass, much easier. The Warren Spring line uses relatively few low powered air fans, which cuts running costs and does away with the need for cyclone air purifiers.

Some 25,000 to 30,000 companies are being approached during the setting up of the waste materials exchange scheme, in which Warren Spring hopes to supplement the existing communication lines of this kind with their quarterly catalogue, which will list the more *outré* waste products, including a good many normally considered toxic but still potentially recoverable. One example has already been the reclaiming of seeds, surplus to requirement which had been given a dressing of a mercuric fungicide; this enabled them to be conveniently recycled into an adhesive for wallpaper, also requiring a fungicide.

Full scale wasteplexes including, as well as pyrolysis plants and sorting lines, specialised centres like that at Pontypool for the reclamation of toxic wastes, and plants for de-inking news print, are perhaps 10 or 15 years away in Britain. But the Oxfordshire study which began in August will soon provide detailed guidelines for such projects which are adaptable for a wide range of districts—Oxfordshire was chosen because of its many and various small industries and life styles.

T. S. McRoberts, Director of the Wolfson Recycle Unit, Queen Mary College, London, describes the background to the unit's work.

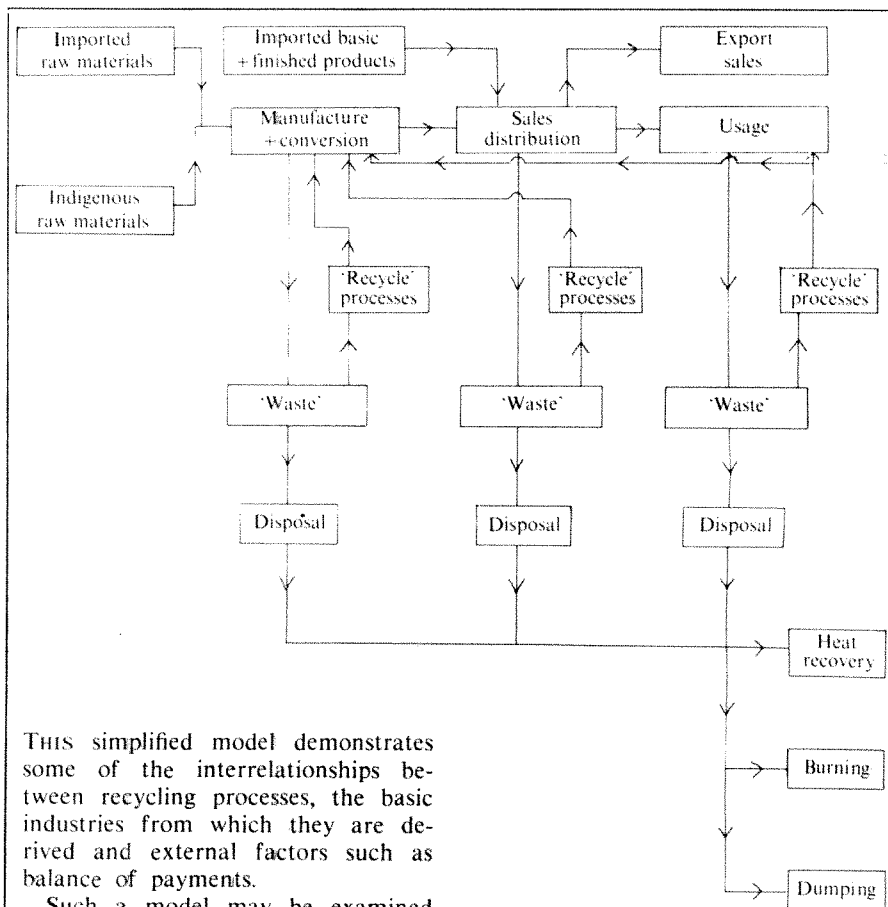

IN ANY study of recycling a great deal can be learnt from what industry is already doing. Many industries already carry out recycling in some form. The chemical industry operates large scale polymerisation plants where the economics of manufacture depends critically on the recycling of monomer. The efficient converter of plastics recovers and reuses offcuts and rejects from moulding operations. The UK paper and paperboard industry finds almost half of its feedstock in waste paper. Yet the bulk of plastics are consigned to municipal dumps after their first use and only about a third of paper is returned to mills for reconstitution and reuse.

Recycling of an obviously profitable nature is already being practised. The most notable example is the scrap metal trade, where an infrastructure of small and large merchants has been built up over many years to feed ferrous and non-ferrous metals back to the smelters. Only the more easily available and profitable sources are tapped, however, and it is estimated that 1 million tonnes of metal are discarded annually into domestic dustbins.

A major obstacle to the reuse of materials has been the cyclical nature of many key industries. At times when business is in the doldrums and mainstream plants are underloaded, prices of products from virgin materials are depressed close to marginal manufacturing costs and the waste recovery industry is immediately jeopardised. Among such industries are the plastics and paper industries, which are the subject of a technical and economic study by our unit.

Both the plastics and paper industries are now entering a recession. The comparatively new plastics recovery industry is under severe economic strain and waste paper merchants have large amounts of expensive working capital tied up in stocks which are proving difficult to sell.

While the waste recovery industry is preoccupied mainly with its own efficiency and profitability, the nation as a whole has a balance of payments crisis linked to heavy importation of energy in the form of oil. The UK imports most of its paper requirements in the form of pulp or finished paper; for example domestic wood pulp accounts for only one-sixth of its wood pulp requirements. The plastics industry depends almost entirely on feedstocks from oil, all of which is at present imported. It is obviously important from a national viewpoint that

THIS simplified model demonstrates some of the interrelationships between recycling processes, the basic industries from which they are derived and external factors such as balance of payments.

Such a model may be examined with several different objectives in mind, such as (1) maximisation of profits to the companies involved; (2) minimisation of energy use; (3) maximisation of exports; (4) minimisation of imports; (5) maximum contribution to balance of payments.

The profitability of a recycling process may be affected greatly by the actions of a government preoccupied by items (2) to (5) as well as by the demand and supply situation for products from virgin material.

A macro model of the type outlined above is a useful accompaniment to any microstudies, since it enables the effect of changes in external factors to be predicted.

the maximum amount of worthwhile recycling of both paper and plastics should take place. The future of recycling in these industries will depend to some extent on a successful formula being found for mitigating the worst effects of economic fluctuations in the primary industries.

The technology of recycling is influenced by the fact that both paper fibres and plastics materials deteriorate in quality in the course of both processing and reprocessing. Each time paper or paperboard is recycled its fibres become shorter and therefore less satisfactory for paper and paperboard products requiring strength. Although this does not appear yet as a limiting factor in recycling, it may well have to be

The basic parameters describing such a model are interrelated and capable of mathematical treatment. Constraints, such as limitation of size of market, can be expressed as inequalities, and mathematical programming can be used to choose between competing procedures or processes on the basis of maximising functions such as profit or minimising functions such as energy and external payments. This model approach can be extended to company level where profit is the main consideration in deciding between alternative processes. It can be used also to guide research into the potentially most rewarding areas.

taken into account as more and more paper is recovered.

The problem of deterioration in quality and performance is much more serious in the case of plastics. Of the two major groups, thermosets and thermoplastics, only the latter can be considered seriously for recycling purposes. The largest outlet for thermoplastics is in packaging, which absorbs 35-40% of production and most of which appears as waste within weeks.

One would prefer to recycle a material back to the use from which it came, but if the material is degraded on reprocessing, so that it is not acceptable for its original use, a crucial question will be the size of the market for the degraded material. □

international news

A TOP-LEVEL advisory committee has told NASA that, unless the agency's dismal budgetary outlook improves, it should take a close look at its plans for planetary research and perhaps even drop or defer two important missions to the outer planets in the late 1970s. The panel makes that suggestion reluctantly because it believes that the expensive planetary flights could squeeze out cheaper, but equally important, missions.

The recommendation, contained in a report prepared by the Space Science Board (SSB) of the National Academy of Sciences, is one of several suggestions about what should be the priorities in space research in the coming years. The report is likely to be highly influential in shaping NASA's science programmes because it was produced by a panel of distinguished (read powerful) astronomers and space scientists with the help of a large number of university researchers. It will be published early in February by the academy.

Starting from the assumption that NASA's space science budget is unlikely to grow much, if at all, in the next few years—an assumption which is borne out by recent trends—the SSB has recommended what it calls a balanced programme by assigning priorities to missions which have already been approved by Congress and, more important, to missions which are still in the planning stage. Although the report says nothing about manned space flight or applications satellites, it assumes that the space shuttle will be developed to put large payloads into Earth orbit.

As far as approved projects are concerned, the SSB strongly supports the High Energy Astronomy Observatories, the Pioneer Venus project and the Mariner Jupiter-Saturn mission, all of which have been reduced in scope and delayed by budgetary restraints. Those three missions, the report says, "represent the next opportunities for important advances in space astronomy and in planetary and lunar exploration." The Pioneer-Venus programme, with the launch scheduled for 1978, is however, already in danger of being delayed by several months as a result of budget cuts proposed by President Ford in November last year, Congress has yet to act on those proposals.

As for projects which are still in the planning stage, the SSB recommends

A blueprint for space research

by Colin Norman, Washington

that a start should be made next year on the Large Space Telescope (LST). An optical telescope which would be flown on one of the early shuttle launches, the LST would, according to the SSB, be "an exciting major step in the history of observational astronomy, observational cosmology and the understanding of the Universe." But it would also be extremely expensive. Consequently, the report suggests that NASA should consider a rather less ambitious LST than it had originally planned to develop.

In short, the LST has been envisaged as a 3-m instrument, but the SSB suggests that it should be reduced to 2.4 m. Even that would, however, be able to detect stars ten times fainter than is possible using ground-based instruments, and it would also have a resolution ten times better. Given the bleak budgetary climate, NASA will probably be only too pleased to take the cut-rate option.

The LST would be the only new start for the next fiscal year, but the SSB suggests that NASA should begin developing hardware for eight other new missions in the fiscal year after that. They are a satellite which would be placed in polar orbit around the Moon, analysis of data from the 1976 Viking Mars Lander mission and planning of further Mars exploration, a spacecraft which would be sent into orbit around Jupiter and which would send probes into Jupiter's atmosphere, a spacecraft which would swing past Jupiter and travel on to Uranus, an orbiting telescope to take advantage of maximum solar activity in the early 1980s, a satellite for infrared astronomy, a gamma-ray satellite and finally, a spacecraft for electrodynamic studies.

Unfortunately, however, if all those projects are given the green light in the 1977 fiscal year, expenditures in subsequent years would probably break NASA's budgetary ceiling. The SSB therefore suggests that if NASA's

budget fails to increase, the agency should either delay developing and launching the Jupiter orbiter for four years or it should scrap plans for the mission to Jupiter and Uranus.

Although both of those projects have considerable support in the scientific community, the SSB says that if they are approved at the expense of high priority programmes in other fields, the space science programme would be unbalanced. Because the launch date of the Jupiter-Uranus spacecraft is tied to a rare alignment of the outer planets, that mission could not be delayed.

Between 1978 and 1982, the SSB recommends that NASA should begin work on a variety of other projects, including an imaging radar which would be placed in orbit around Venus, orbiters around Jupiter, Mercury and Saturn, a spacecraft to intercept the comet Encke, another infrared telescope, a 1.2 m orbiting X-ray telescope, and possibly a spacecraft which would travel out of the ecliptic plane.

The report makes clear that there is a difference of opinion among planetary scientists about the exploration of Mars after the 1976 Viking lander mission. The report recommends that a long term goal should be to bring samples of the surface of Mars back to Earth for analysis and inspection, but that the next stage of exploration should be to place a spacecraft in polar orbit around the planet, and to follow that with a probe and hard lander in the early 1980s. An SSB subcommittee on planetary research urged, however, that existing spacecraft should be modified so that another Viking lander could be despatched to Mars in 1981 if the 1976 mission produces particularly exciting results. But the SSB report said that keeping such an option open would be too expensive. "we see no missions that should be displaced to meet such option costs", the report states.

The missions recommended by the SSB would keep NASA's space science budget essentially the same in terms of purchasing power over the next six or seven years, but with inflation running at its present rate and President Ford preaching fiscal restraint, it remains to be seen whether even that modest expectation will prove to be too optimistic. There should be some clues when the Administration publishes its 1976 budget recommendations on February 3. □

Canada adopts new nuclear safeguards

from David Spurgeon, Ottawa

STUNG into reconsidering its nuclear export policy by India's explosion of a nuclear device last year, Canada has announced that more stringent safeguards will now be applied to sales abroad of its nuclear technology, facilities and material. But, instead of calling for a complete ban on nuclear sales—as it once considered doing during a seven-month policy review—Canada has decided actually to encourage such sales provided new safeguards are met.

The decision has considerable importance. The Indian explosion (achieved with the unintended aid of a Canadian research reactor and personnel training programme) embarrassed government officials here just at a time when the CANDU reactor's remarkable success at home was beginning to pay off in export sales. By stirring Canadian consciences with the threat of further nuclear weapons proliferation, the Indian incident threatened to frustrate one of the country's few successful forays into high technology just when the superiority of CANDU was being proved.

To some observers, the prospect of Canada failing fully to exploit commercially a successful technology, after the expensive research and development had been accomplished with government funds, seemed balefully familiar.

The government's rationale for its new policy, announced on December 20 by the Minister of Energy, Mines and Resources, Donald S. Macdonald, was thus to place in balance the need for foreign trade of the Canadian economy, the need for cheap electrical power of developing countries at a time of world-wide oil shortage, and Canada's responsibility for ensuring that her nuclear resources do not contribute to the proliferation of nuclear weapons.

"The provisions, to be administered by the International Atomic Energy Agency, or through appropriate alternative procedures meeting the requirements of the Treaty on the Non-Proliferation of Nuclear Weapons", said Mr Macdonald, "will cover all nuclear facilities and equipment supplied by Canada for the life of those facilities and equipment."

"They will cover all nuclear facilities and equipment using Canadian-supplied technology. They will cover all nuclear material—uranium, thorium, plutonium, heavy water—supplied by Canada, and future generations of fissile material produced from or with these materials. They will cover all nuclear materials, whatever their origin, produced or processed in

facilities supplied by Canada."

"Most importantly, all safeguards arrangements will contain binding assurance that Canadian-supplied nuclear material, equipment and technology will not be used to produce a nuclear explosives device, whether the development of such a device be stated to be for peaceful purposes or not."

This latter remark was a reference to the Indian case, in which that country claimed not to have violated previous agreements with Canada because her nuclear explosive was for "peaceful purposes"—an interpretation never agreed to by Canada but now explicitly excluded for the future.

Potential Canadian exporters of nuclear material, equipment or technology were advised that in future they will have to ascertain from the government that there are no safeguards or impediments to sales before making offers of supply.

Having outlined the safeguards, Mr Macdonald said that, "to ensure that Canadians will enjoy the economic gains from sales abroad, the government will encourage the supply from Canada of major high technology components and services." It would also seek domestically to "establish a cooperative approach of preference (among the provinces) for Canadian material equipment and services."

The Canadian industry at present has the capacity to produce at least three nuclear reactor power systems a year, the minister said. Domestic requirements will average four units a year over the remainder of the decade, and exports could add at least one additional unit a year. Nearly \$100 million in capital investment has already been committed or planned by the private sector to expand capacity, and future demands will require perhaps \$100 million more. The federal Department of Industry, Trade and Commerce will see if it can help provide it through incentive programmes.

Meanwhile, the government has lifted the freeze put on nuclear exports after India's explosion and has authorised Atomic Energy of Canada Limited to negotiate a number of foreign sales and agreements, provided that they comply with the new safeguards.

These include agreements with the United Kingdom covering CANDU/SGHWR technological exchanges and heavy water supplies, a licensing agreement to supply CANDUs to Italy, goods and services estimated at \$150 million for a second 600-MW CANDU power station for Argentina, two 600-MW CANDUs for Iran—possibly four, one reactor for Korea, the nuclear part of a CANDU for Denmark, and technology agreements with Rumania.

Opposition parties have said that the new policy does not go far enough to prevent the spread of nuclear weapons. James Balfour, of the Progressive Conservatives, said nuclear agreements should not be signed unless the country involved allowed inspection of all its nuclear facilities, not just those acquired from Canada. This would prevent countries from simply copying a CANDU and using it to produce plutonium.

But Mr Macdonald claimed that the new policy makes Canada's safeguards standards higher than those of its competitors—and only time will tell if that will hurt sales. He said that International Atomic Energy Agency safeguards do not cover technology or prevent the use of nuclear materials for peaceful purposes, as Canada's now do.

In the last analysis, of course, everyone recognises that no form of international agreement will guarantee non-proliferation of nuclear weapons, that depends upon each nation's willingness to abide by the agreements. Mr Macdonald admitted as much outside the Commons after his announcement. And if trade partners with Canada decide to break their agreements, he said, Canada will have no recourse but to embargo future nuclear sales, as was done with India. □

Useful, unsurprising

THERE are no surprises in the recent report on energy conservation prepared by the National Economic Development Office (*Energy Conservation in the United Kingdom*, HMSO, £3.40) but a useful collection of relevant facts and figures which have been lacking in some other surveys.

As expected the report pinpoints domestic and office heating as the main areas in which savings can be made without too much social upheaval, and suggests a comprehensive analysis of the type of fuel and energy supply which would give the most efficient use of primary energy. The facts show that the net energy supply to the domestic market increased very little from 1960 to 1972, although the pattern of fuel use changed drastically. About 70% of this energy goes into space heating, and as the number of homes is steadily increasing and the population is changing to include a greater number of elderly people who will require higher living temperatures, the greatest savings in energy demand can be made here by a much more widespread use of proper insulation. An energy saving of 22% for a new three-bedroomed, semi-detached, centrally heated house could be achieved at an extra cost of a few hundred pounds a house. □

THE long awaited verdict on whether or not the artificial sweetener saccharin causes bladder cancers in rats may still be several years away. Last week, a committee of the National Academy of Sciences, which had been examining the evidence for two and a half years, said that there is not enough reliable data to state that saccharin is or is not a carcinogen. Consequently, the Food and Drug Administration (FDA) announced that it will do some more tests and continue to freeze consumption of the sweetener at 1972 levels.

The academy's report, which presents a detailed analysis of the history and chemistry of saccharin as well as a searching critique of the carcinogenicity tests, leads, however, to two disturbing conclusions. The first is that there has been a scandalous lack of study by the FDA of a chemical which is consumed by about 12 million people in the United States, at the rate of some five million pounds a year. And the second is that most of the saccharin produced in the United States is contaminated by an impurity, *o*-toluene-sulphonamide (OTS), which could itself be a carcinogen. The latter possibility may not only have distorted carcinogenicity tests on saccharin, but it also raises the question of why the FDA has not taken steps to determine the biological significance of OTS and, if necessary, to ensure that the sweetener is manufactured in such a way that the impurity is kept out.

If OTS is, indeed, a carcinogen when fed to animals, the so-called Delaney amendment to the Food and Drug Laws would require that saccharin contaminated by OTS must be banned from the market. Saccharin is manufactured by two commercial processes, the most widely used of which produced OTS impurities at the level of several hundred parts per million, whereas the other results in contamination of only a few parts per million.

There have been two principal studies which raised fears that saccharin may cause bladder tumours in rats. One was carried out by the FDA itself and the other by the Wisconsin Alumni Research Foundation (WARF)—a laboratory supported by the sugar industry. Both studies revealed increases in the incidence of bladder tumours in rats fed saccharin at doses of 7.5% and 5% of the daily diet. The sweetener was administered to pregnant rats so that their offspring were exposed before birth, through the mother's milk and subsequently in their own diets.

The academy committee points out, however, that because the rats were also getting OTS "at very large dose levels", it is "impossible to say whether

saccharin itself was the carcinogen". The report also raises the question of whether bladder stones and parasites may have played a role in the formation of tumours. But, on the other hand, the academy report notes that most of the tests which have produced no evidence of carcinogenicity did not involve exposure to saccharin *in utero*. Therefore, they "cannot be interpreted as showing that saccharin is not a bladder tumorigen".

The FDA study and the WARF study were completed early in 1973,

Washington seen

by Colin Norman

but an FDA scientist acknowledged last week that the agency has sponsored no more tests since then, even though doubts have been raised about the role of OTS. The academy therefore recommends a series of studies to investigate the significance of impurities in commercial saccharin and the role of parasites and bladder stones in tumour formation, and epidemiologic studies to see whether there is any relation between cancer and long term consumption of saccharin in man. Dr Julius Coon, of the Thomas Jefferson University in Philadelphia, who was the chairman of the academy committee, said last week that the tests could take about two years to complete.

● No action of Mr Nixon's upset the elders of science in the United States more universally than his decision to shift responsibility for formulating science advice from the White House to the bureaucratic hinterlands of the National Science Foundation. President Ford's announcement last month that he has set Vice-President Rockefeller the task of determining what arrangements should be made for getting science advice to the President was therefore greeted with considerable enthusiasm. But, with Rockefeller occupied in trying to determine the truth of allegations that the CIA indulged in domestic activities, the operation has taken something of a back seat. Henry Diamond, a lawyer connected with Mr Rockefeller's Critical Choices Commission in New York, has been given primary responsibility for the study and some announcement is expected

within the next month or so.

A number of groups, including the National Academy of Sciences and the US Senate, have publicly endorsed the view that a science policy apparatus should be re-established in the White House, and it seems likely that the Rockefeller study will recommend such a move. A key issue, however, will be the extent to which the mechanism will have influence over military research and development—when Nixon scrapped the old arrangement he specifically told the National Science Foundation to keep out of military affairs. And another central factor is how it will interact with the Office of Management and Budget. It is understood that those questions are now being debated among Rockefeller's advisers.

● A Boston physician went on trial last week faced with a manslaughter charge for allegedly killing a foetus during an abortion he performed last year. The trial has drawn considerable attention throughout the United States because it is likely to define in more precise terms when a foetus should be considered capable of surviving independently from its mother.

The physician, Dr Kenneth Edelin, was charged last year by a grand jury of aborting a foetus—described in the charge as a "baby boy"—which was believed to be between 24 and 28 weeks' old, and of failing to take steps to assure its survival.

When the Supreme Court handed down its historic decision on abortion two years ago, it ruled that state laws cannot forbid abortions before the foetus is 'viable', but it deliberately left fuzzy the definition of what constitutes viability. Its decision, in fact, is a model of obfuscation, since it states that viability "is usually placed at about seven months but may occur earlier, even at 24 weeks". The foetus that Edelin aborted is right in that uncertain period, and the trial is therefore likely to hang on the definition of viability.

But, aside from defining more precisely the scope of the Supreme Court's abortion decision, the trial could also have some implications for foetal research. There have, during the past year or so, been several state and national laws enacted which attempt to put a stop to research involving so-called living foetuses, but those laws have largely been passed in the absence of any definition of what constitutes a living foetus. They are generally regarded as greatly restricting some important areas of biomedical research.

The trial is expected to last for four or five weeks, and Edelin could face a lengthy prison term if found guilty.

Moves to set up a register of toxic chemicals

from Peter Collins, Geneva

THE first practical steps towards setting up an international register of potentially toxic chemicals were taken at a meeting at Bilthoven, The Netherlands, this month. Sponsored by the United Nations Environment Programme (UNEP), and hosted by the Netherlands Government, the meeting marks an unexpected change of mood on the part of governments in their approach to a subject which, when raised at the preparatory committee for the Stockholm Conference on the Human Environment, seemed one of those on which early action was least likely. During the committee's discussions the suggestion for such a register had a consistently lukewarm reception, especially from those governments most able to contribute to it. This was largely because of a feeling that so many sensitive areas of industrial confidentiality and, probably, military security were involved that real co-operation on the part of both manufacturers and governments—as users of many candidate materials—would be virtually impossible to achieve.

There has evidently been a big change of attitude, especially on the part of governments, though not yet so visibly on the industrial side. Perhaps the principal reason for this is the sheer pressure under which governments have found themselves when it comes to testing the enormous number of new potentially toxic substances being produced each year, the position of which needs to be defined with regard to the increasingly large and strict body of legislation in many countries, itself in part a result of pressure arising from the atmosphere of the Stockholm Conference.

Governments, it would seem, no longer have the same attitude to confidentiality over much of this field as they did two or three years ago. The more details are made public, the greater is the chance of making widespread testing of potentially dangerous new products more effective, if information is more widely available, testing to acceptable standards can be carried out cooperatively, and the number of candidate substances covered in a given time can be greatly increased. Governments, in fact, are facing a situation in which they cannot, working individually, keep up with their own requirements, since testing to modern standards is so lengthy and costly a process, and a situation already exists

where virtually all the testing is being done in a small group of countries, working informally on behalf of a much larger number of governments. Any facility to help the pooling of information, such as could be provided by an international register, would at least tend to avoid duplication.

As regards industry, it would seem that the gloomy view of the prospects of collaboration at the time of the Stockholm Conference was based on a misconception. The problem is not that industry keeps quiet because it has so much dangerous information to hide. In fact, industry does very little testing beyond a certain point at present, leaving the finer details to governments. What could well be hidden by industry, the UNEP believes, is ignorance of the toxic properties of its own products, rather than information about known dangers. It looks almost as if many companies are keeping quiet because they know so little, not too much.

For these reasons, the proposed register is predicted by the UNEP not on industrial information, but rather on that which is already, and which will be needed, on an international exchange basis. Here again, governments remain the key to the provision of information on which to base any realistic international register.

Some national, and even international, registers do already exist. They vary widely in scope and detail, and help to show up some of the problems that will be involved in any project such as the one the UNEP has in mind. Thus, a list of toxic substances published in the US for the year 1973 runs to nearly 1,000 pages and covers more than 10,000 preparations—none of them described in such detail as the UNEP believes to be necessary for the sort of register it is aiming at. At the other end of the scale come the monographs put out by the International Agency for Cancer Research at Lyons, which now covers more than 100 compounds. These are as complete as could be wished.

In the UK, thinking on how to respond to the UNEP initiative is well advanced. Acting on the advice of the Royal Commission on Environmental Pollution, and of the Royal Society, the Department of the Environment has engaged the UK Chemical Information Service to design and develop a Network on Environmentally Significant Chemicals—DESCNET. This will be so designed as to provide input to, and to draw on, the UNEP International Register. In general, however, the approach in the UK will be selective and will utilise existing systems and data wherever possible.

Meanwhile, the UNEP feels that response to its initiative is widespread. Especially gratifying has been that from

the developing countries, which have a huge problem, inasmuch as they are not, with one or two exceptions, in a position to do any testing for themselves, and have to rely on what information they can gather from published reports or private enquiries elsewhere. The presence of representatives of the Soviet Union and the East European countries, however, perhaps interests the UNEP more at this stage, since there is the hope that from them, at least, information from industry may be available—as it should be, all industry being under government control.

The present meeting differs from previous consultations in this field in another respect: the majority of participants are people actively working on the problems of toxicity or in allied fields, or already concerned in compiling national registers, rather than official government representatives as scientific or administrative civil servants.

Moreover, the common denominator at Bilthoven is the chemical *per se*, not "the chemical in the environment"—in fact, an almost essential approach if the discussion, and the register that is its eventual objective, is to deal with the potential toxicity of new compounds, as well as with the hazards known to attend the use of those already in production. The aim, if the proposed register is to fulfill its purpose, is to satisfy the need for the unambiguous identification of chemicals, and of the dangers that may attend their use, if only because, unless such information is available, it is not possible to computerise the data—and the amount of information will certainly be such that it cannot be handled in any other way. So the intention is not just to list substances that are, or may be, released to the environment, but all sorts of potentially toxic substances, regardless of their categories of use.

Finally, although industry may at present seem to be reacting rather coyly to the idea of such a register, there is little doubt of a basic willingness to collaborate. This is not only because most companies involved in the production of candidate substances are anxious to improve their public image in this respect. It is also evident that while not at present likely to be providers of much information for the register (largely because they do not have the facts required), they will certainly be among the most concerned users of its outputs. The important thing is that we now have the chance of developing an orderly mechanism, internationally and nationally, for assembling an up-to-date dossier on chemical substances as a basis for environmental management and decision making. □

correspondence

Czech persecution

SIR,—I wish to raise some points about Professor Burhop's letter (November 22) Does he know about the existence of a law in Czechoslovakia, which is much more iniquitous than the one which may be accepted in West Germany? This is the Labour Code (law 42/1970), which contains section 46, lett e, according to which a notice could be given to anyone who "violates the socialist social order" In the past five or six years tens (if not hundreds) of thousands of Czechoslovak citizens have lost jobs not only at schools, universities and justice offices, but also in the research institutes, mass media, theatres, publishing houses, museums, state administrative departments and so on because of the application of this paragraph

Having been dismissed myself from the Nuclear Research Institute in 1970 under this paragraph, I tried to get revocation of my notice through the law I shall quote here from the decision of the Court of Appeal, the highest authority in such cases

"The claimant's activity was violating the socialist social order as he signed a resolution which demanded a change in the system of the leading organs (of the Academy) Furthermore, the claimant tried to damage the development of educational and cultural policy of our state, which is led and directed by principles of Marxist-Leninist ideology, and this he did for instance when he pleaded for the abolition of censorship of scientific publications"

Does the World Federation of Scientific Workers raise its voice against this law, which has been in force in Czechoslovakia for many years?

Professor Burhop's version of the shameful persecution of Malek is incorrect Section 11 of the Czechoslovak pension law states that "persons who have reached the age of at least 60 enjoy a right to be retired" No obligatory retirement age is given in the law about the Czechoslovak Academy of Sciences (54/1963)

Professor Malek's contract with the academy had not been extended in October 1973, and Malek had either to find a new job or to retire (in 1970, as a measure of political persecution, the time limited labour contracts had been introduced in the Czechoslovak Academy of Sciences—20, 4, law

26/1970—for senior scientists only The duration of contracts ranges from three months to four years) This dismissal has been an act of purely political persecution or even revenge In contradiction with world academic habits, he does not enjoy the right to keep his office or laboratory in his former institute, he is now not even allowed to use the institute library

I agree completely with Burhop's statement that issues like the retirement age should be "matters for the people of that country to decide" Is he not aware of the fact that the people of my country lost the right to decide on their own fate on August 21, 1968, when our country was invaded by foreign troops which were occupying my homeland?

The plight of Czechoslovak scholars and intellectuals is a direct consequence of this One should not forget it

F JANOUCH

Copenhagen, Denmark

SIR,—I would like to comment on the discussion between Professors Janouch and Burhop (August 9 and September 20) concerning the situation of scientific workers in Czechoslovakia

I absolutely agree with Janouch that "only open, public stands, protests and statements are meaningful and helpful" This is not only based on my own experience while living under this regime but also on experience during work with other institutions, such as Amnesty International There is no doubt that the procedure suggested by Burhop might be effective with some regimes which respect—at least to some extent—reasonably open discussion This is, however, certainly not the case in the so-called people's democracies, where the hypocritical Party bureaucrats not only suppress any sort of criticism but do not even respect their own constitutions and laws

To illustrate the absurdity of the present situation of scientists in Czechoslovakia, I would like to bring up one flagrant example concerning Mr Karel Kriz, a former senior lecturer at the Technical University at Brno (Moravia) Like many of his colleagues, he was dismissed from his position because he declined to accept the Russian occupation as brotherly help For some time he was not able to find any reasonable employment, in 1972, however, he started a "new career" as a buyer dealing in rabbit skins for the national enterprise KARA Since this job was

not very well paid, he was compelled to organise his business using (for Czechoslovakia) new commercial methods he sent various posters and information leaflets (on the eminent importance of rabbit skins for the national economy and so on) to all villages in the southern part of Moravia and informed the inhabitants of his impending arrival In fact, he organised a group of gypsies, who regularly visited all villages and bought up rabbit skins for him and therefore for KARA One of his posters read

Dear friends

KARA purchases hides and skins of every description I shall be calling at your village once a fortnight Kindly have your goods ready for me, Thank you for your cooperation

Your skin buyer

Independent scientific worker

Doc Ing Karel Kriz, Candidate of Sciences, skin buyer for KARA, national enterprise

His action soon became a great success, and the gypsies, villagers and KARA were exceedingly satisfied Even the Party bureaucrats paid tribute to the successful gypsy brigade, which was soon accepted as one of the best "brigades of socialistic labour"

The disaster came in the summer of 1973 in the form of a panel discussion on Austrian Television devoted to the brain drain At the end of the discussion, in which the Prime Minister, Dr Bruno Kreisky, also took part, the commentator said (ironically) that some neighbouring countries had succeeded in solving this problem better than Austria had At the same time he showed Mr Kriz's poster

Two days after the panel discussion, Mr Kriz was arrested on a charge of damaging the interests of the Republic, according to Section 112 of the Penal Code ("A Czechoslovak citizen who damages the interests of the Republic by spreading or enabling to spread in other countries false reports about conditions in the Republic will be punished with prison up to three years") The first trial, which should have taken place in November 1973, was postponed, and in the autumn of 1974 Mr Kriz was sentenced to three years in prison, the maximum punishment What for? After all, the text of the posters was

approved by the censor and according to the law, nothing can prevent Mr Kmz from using his scientific degrees

I would like to end by appealing to all scientists who are lucky enough to live in free democratic countries please, do help actively our colleagues who are deprived of their human rights and are kept in prisons or are dying slowly in concentration camps and psychiatric hospitals, no matter where. If we do not help them, nobody will. After all, passive humanitarianism helps no one except the totalitarian regimes

E. ANTONCIK

University of Aarhus, Denmark

Trieste centre

SIR,—We must indeed be grateful for the letter from Sir David Martin and Mr Cozens (December 20/27) on the policy of the Royal Society UNESCO committee concerning the International Centre for Theoretical Physics (ICTP) at Trieste. Many of us who have been closely connected with the scientific programmes of the ICTP were relieved to learn that the British delegate to the recent UNESCO General Conference praised the centre, and voted for the full proposed financial contribution from UNESCO for 1975 and 1976. To that extent, at least, we have succeeded in our efforts (such as the meeting of the Royal Society on May 16, 1974) to ensure that this committee is fully informed about the work of the centre and is no longer taking decisions without reference to ascertainable opinion amongst British physicists.

The last paragraph of this letter further invites comment on the policy with which the British UNESCO delegation should approach the proposed review of "UNESCO's relations with and subvention to the centre". It is to be hoped that this policy will not be decided without thorough consultation, by the whole committee, with those who understand the situation at Trieste.

A kite is being flown, for example, that the ICTP could be financed mainly by direct contributions from individual governments or national scientific organisations, thus taking the burden from United Nations agencies such as UNESCO and the International Atomic Energy Agency (IAEA). This would be a disaster. As I thought was obvious from my article in *Nature* on March 22, the administrative resources of the ICTP are quite inadequate to the solicitation and collection of such contributions. It is able to carry out a valuable scientific programme on behalf of all nations, without serious political disruption, because it is a technical instrument through which a small number of international agencies (including the UN Development Program and the Swedish International Development Agency) channel their

efforts. Additional contributions from individual governmental organisations, such as Britain's Science Research Council, are very welcome, and are not inappropriate considering the scientific work that is actually done at Trieste by physicists from Britain and other advanced countries, but there is no substitute for the basic budget, shared by UNESCO, the IAEA and the Italian Government, that keeps the centre in active being. The real questions, rather, are the formal place of the contribution to the ICTP in the UNESCO budget, and the administrative devices by which it is maintained as a permanent institution within both UNESCO and the IAEA.

In view of the time and trouble it has taken in the past to get the facts about Trieste across to the British UNESCO delegation, it is not too early to air these issues in your columns (or in some suitably ventilated corridor!) in preparation for a wise decision in 1975 or 1976.

Hungarian attitudes

SIR,—Dr Peller's Hungarian experience (December 13) will only surprise those who believe that Hungary is a 'liberal' east-block state. In a very restricted sense this is true, but life for research workers in Hungary is difficult, and especially so if they intend to travel westwards. Outward evidence of the internal situation is shown by the difficulties Western scientists sometimes encounter if they want to travel in Hungary. As a former coworker in a research institute in Budapest, I had the opportunity of participating in the Conference of Solid State Physics held in Manchester in January 1966. I also intended to make a contribution and, as is the usual case in Hungary, I should have received by passport just one day before my travel. On that very day the Ministry for Metallurgical and Engineering Industry, my 'higher' authority, told me that I would not get a passport. No reason for this decision was given. This was only one typical case among several similar ones during the 17 years of my scientific career in Hungary. In general, for a young scientist, professional travels to Western countries are possible only if he is 'politically reliable'.

Undoubtedly only few entry applications are rejected. Israelis are especially not welcome, probably because of the great number of Jews living in Budapest, who might get authentic information on the real situation in the Middle East. Western scientists who have participated in a conference in Hungary, however, are in general delighted by the traditional hospitality of the organisers and this

helps to mask the autocratic treatment of the international scientific communities by the authorities.

LAJOS ERNST

University consultancy

SIR,—I would like to support Mr H. A. Cook's letter (December 13). Although I am not certain that all consultancy by university staff should be discouraged, for after all this is one way in which the results of research are transferred to industry, I am more particularly concerned at the use of university facilities for the production of hardware for commercial purposes.

In this company we are aware of at least two instances in which companies have been formed by university staff to manufacture equipment which is in direct competition with some of our own products. We are also aware that these companies have no manufacturing facilities of their own and that university plant, equipment and man-hours are used in the production of this equipment.

In effect, such companies have extremely small overheads which makes competition very difficult for a company like ours where all the research and development work must be paid for from profits.

I agree completely with Mr Cook that the appropriate government department should put a stop to the extracurricular activities of those university staff who, in effect, are being paid two salaries for doing one job and are using public funds under false pretences.

Periodic unification

SIR,—In your issue of October 25, page 661, paragraph three, there appeared an anonymous quotation and comment about the reception of some of Mr Edward Haskell's work, referring to a conference held in New York in 1971. The item "'We had to listen to some extraordinary ideas of unification by way of Mendeleev's periodic table' said one participant. Another was horrified that whilst the scientists thought it silly, the philosophers present took it very seriously." I wish to set the record straight. There may have been more than one scientist who thought Haskell's work silly—blindness that was found in attitudes of some scientists towards precursors of Mendeleev's table. I can, however, certify that not only the philosophers present but also a number of highly qualified scientists who were also there, and who read Haskell's work, take it very seriously indeed.

Protein turnover in the whole body

from J C Waterlow

In this issue of *Nature* (page 192) Young and co-workers at the Massachusetts Institute of Technology report measurements of the rate of protein synthesis in the whole body in human subjects from birth to old age. This is a timely contribution to a topic which is attracting increasing attention, and which has lain fallow for some time. It is 35 years since Schoenheimer, Ratner and Rittenberg (*J biol Chem*, **127**, 333, 1939) reported "the first experiment in which one amino acid of a normal diet, tyrosine, has been labelled by the nitrogen isotope". In subsequent papers the concept of protein turnover was firmly established, but it was not for another 10 years that attempts were made by two groups, that of Rittenberg at Columbia and of Wu in Alabama, to measure the overall rate of this process in the whole body (Sprinson and Rittenberg, *J biol Chem*, **180**, 715, 1949; Wu and Snyderman, *J gen Physiol*, **34**, 339, 1950). In these early studies the method used was to give a single dose of an amino acid labelled with ^{15}N and to calculate the rate of turnover from the curve of ^{15}N excretion over the next 48 hours or so. It was soon realised that such a calculation is erroneous: the shape of the early part of the excretion curve is the resultant of a large number of processes, and cannot be analysed in a meaningful way. After the first few hours the slope is determined largely by the turnover rate of urea and not by that of protein.

From this point development occurred in two directions. Olesen *et al* (Olesen, Heilskor and Schønheyder, *Biochim biophys Acta*, **15**, 95, 1954) measured ^{15}N excretion in urine for 15 days after a single dose of ^{15}N -glycine, and calculated the rate of protein synthesis by multi-compartmental analysis. Theoretically this method is an improvement on the earlier ones, in practice it has not been followed up, presumably because of the difficulty of maintaining a constant nitrogen intake and a steady state in subjects other than healthy volunteers. San Pietro and Rittenberg (*J biol Chem*, **201**, 457, 1953) took an opposite line. They devised a method which depends on measuring the maximum ^{15}N abundance in urinary urea after a single dose of ^{15}N . Peak labelling occurs about 3 hours after the dose, and the calculation of

protein turnover depends upon this interval being accurately timed. In fact it is impossible, from measurements on urine, to know precisely the time at which maximally labelled urea was synthesised. The method is therefore unsound. In spite of this it was quite widely adopted in subsequent years to study protein turnover in various pathological states such as pituitary and thyroid disease. But the results in normal subjects showed a wide scatter, and nothing of interest was revealed in patients with metabolic disease. Probably for this reason interest in the subject waned. It is unfortunate that the method most widely used was the least reliable.

Nothing more seems to have been attempted for about 10 years until Picou and Taylor-Roberts (*Clin Sci*, **36**, 283, 1969) working on malnourished infants in Jamaica, used a continuous infusion of ^{15}N -glycine to produce an isotopic steady state. If nitrogen balance is measured as well, total rates of both synthesis and breakdown can be calculated. This is the method which six years later has been used to good effect by the workers at MIT. It probably gives more accurate estimates of total protein turnover than the older methods, but problems remain. On theoretical grounds a likely source of error is that even in the steady state the labelling of amino acids in the precursor pool for urea synthesis may not be the same as that of amino acids for protein synthesis. The report of Young *et al* suggests however that the method gives results which at least have comparative meaning. Moreover, the value for protein turnover in normal adults, of $3 \text{ g kg}^{-1} \text{ d}^{-1}$ agrees well with results obtained by infusion of radioactive amino acids, whereby the special problems associated with urea formation are avoided (James, Sender, Garlick and Waterlow, unpublished).

It seems reasonable to suppose that

the difference in turnover rate in infants and adults is related at least in part to growth. A major contributor to whole body turnover is the turnover rate of muscle protein. Table 1, from unpublished results of D J Millward, shows the rates of synthesis and breakdown of muscle protein in rats of various ages. The difference represents net growth of muscle protein. Rapid rates of growth are accompanied by rapid rates of turnover. From the energetic point of view this is a costly process. The energy cost of protein synthesis is not negligible, estimates range from about 4 kJ per gram, based on the requirement of 4 moles ATP+GTP per mole peptide bond, to about 30 kJ per gram, derived from nutritional measurements. Whatever the true figure *in vivo*, it looks as if protein turnover must account for a considerable part of the basal energy expenditure. A general relationship was suggested between rates of protein turnover and of basal metabolism (Waterlow, *Lancet*, **ii**, 1091, 1968) and Young's work confirms this.

There remains a substantial gap between rates of protein synthesis at the subcellular level and in the whole animal. The information that is becoming available about synthesis rates *in vivo* shows that the efficiency of synthesis (g protein synthesised per g ribosomal RNA) in subcellular systems is perhaps 100 times less than the efficiency in the whole animal (Henshaw *et al*, *J biol Chem*, **246**, 436, 1971; Millward *et al*, *Nature*, **241**, 204, 1973). Until this difference is reduced, we can rely on subcellular systems for information about mechanisms but not about rates. A major problem for the future is to understand the means by which rates of protein turnover are controlled. It is perhaps provocative to suggest that, in spite of all the difficulties, a solution is most likely to come from studies on the whole animal.

Table 1 Rates of muscle protein synthesis, breakdown and net growth in normal hooded rats at different ages

Age (d)	Fractional rate (% d ⁻¹)			Efficiency of synthesis (g protein/g RNA/d)
	Synthesis	Breakdown	Net growth	
23	28.6	22.4	6.2	19.2
46	16.1	13.1	3.0	14.2
65	11.5	9.8	1.7	13.8
130	5.3	4.6	0.7	10.1
330	4.9	4.6	0.3	11.5

Antibody structure and antigen binding

from C C F Blake

ONE of the major problems in immunology has been the reconciliation of the structure of antibodies with the vast range of antigen binding properties they possess. The long and patient study of antibody structure by chemical methods has produced a basic framework for the solution of the problem by showing that antibody molecules have the following features: (1) the molecules are built from two identical heavy chains of ~440 residues and two light chains of ~220 residues, linked together by disulphide bridges, (2) there are four repeating homology regions or domains of ~110 residues in the heavy chains, and two in the light chains, (3) the amino-acid sequence of the N-terminal domains is variable, (4) the sequence in the rest of the molecule is more constant and allows the chains to be characterised as κ and λ light chains which can associate randomly with α , γ and μ heavy chains to give respectively the IgA, IgG and IgM major isotypic classes of antibody molecules, (5) within the variable sequence there are hypervariable regions. This information has been seen to imply that antibody molecules have a common basic structure, in which the antigen binding function is carried by the variable domain whose hypervariable regions are involved in the binding process.

For several years protein crystallographers have been seeking to give this elegant and satisfying model its final structural definition, and at the same time to provide a molecular description of the binding site and its mode of interaction with antigen. As with other studies in this field the work has been hindered by the heterogeneous nature of antibodies and to some extent by the size of the molecule. The former problem has been overcome in the usual way by using myeloma proteins, and the latter, although preliminary X-ray studies on whole immunoglobulins have been reported, by utilising fragments of the molecule, either the papain-induced Fab fragment which contains the binding site, or the naturally occurring Bence-Jones protein, a dimer of the light chains.

In the last year or so, four groups have independently reported high resolution structural analyses of these fragments. Poljak and his colleagues have worked on the Fab fragment of human IgG1 New (Poljak *et al*, *Proc natn Acad Sci USA*, **70**, 3305, 1973; Poljak *et al*, *ibid*, **71**, 3440, 1974), Davies and his group on a similar fragment of mouse IgA, McPC 603 (Padlan *et al*, *Nature new Biol*, **245**, 165, 1973; Segal *et al*, *Proc natn Acad Sci, USA*, **71**, 4298, 1974) and the groups led by Edmundson (Schiffer *et al*, *Biochemistry*, **12**, 4620, 1973) and Huber (Epp *et al*, *Eur J Biochem*, **45**, 513, 1974) have each solved

a human Bence-Jones protein. In confirmation of the chemical model all four groups report essentially similar tertiary and quaternary structures.

In the X-ray models the homology domains of ~110 residues appear like beads threaded on a string. Each domain has a tertiary structure that is basically two parallel β sheets between which is the hydrophobic core. The intrachain disulphide bridge, which is a characteristic of each domain, links strands in opposite sheets so that the two sulphurs are located near the centre of the domains. In the constant domain one sheet has four strands and the other three, the variable domain has an additional loop that extends the three-stranded β sheet of the constant domain to five strands. The link between the two domains is made by a short extended chain segment called the 'switch' region.

Each domain associates non-covalently with an equivalent domain in the other chain: the Fab has $C_{H1}C_L$ and V_HV_L dimers, and the Bence-Jones C_LC_L and V_LV_L dimers. This domain dimerisation has two unexpected features. The constant domains associate so that the four-chain sheets are closely opposed and their strands approximately perpendicular, but the variable domains oppose the other β sheet (the one with five strands) which leads to a looser association and a greater intersheet spacing. In the association each domain is related to the other in the pair by pseudo two-fold symmetry, but all four groups have found that the axes of symmetry between the pairs of constant and variable domains are far from colinear, angles of intersection between 120° and 135° are reported. As a result the switch regions bend through different angles in the two chains to give the four domains a tetrahedral arrangement. Although this is not altogether surprising in the Fab where the four domains are chemically distinct, the lack of structural equivalence between the chemically identical chains of the Bence-Jones proteins has led Schiffer *et al* to suggest that one of the two light chains in the molecule fulfils the structural role of the heavy chain in Fab. This suggests that Bence-Jones proteins are counterparts of the antigen binding regions of immunoglobulins and may themselves have functional binding sites.

The close similarity of tertiary and quaternary structure observed in the Fab fragments and the Bence-Jones proteins strongly implies the invariance of many features in the architecture of antibody molecules, and allows some important predictions to be made. The amino acid homology between the C_{H2} and C_{H3} domains of the Fc fragment and the C_{H1} domain of Fab makes it

highly probable that the X-ray analysis of Fc now under way will reveal an equivalent structural homology. Poljak has shown from his results that the intrachain disulphide bridge in human γ_2 , γ_3 , γ_2 and μ chains, which is shifted by 83 residues on the heavy chain from its position in the γ_1 heavy chain in his molecule, can be made without altering the observed folding of the polypeptide chains. He also shows that a number of additional or unusual disulphide bridges which have been observed are made between residues that are already in the appropriate orientation. This is additional strong evidence that the results we already have in the Fab parts of the molecule provide the structural basis for all other classes of antibody molecule.

The properties of the antigen binding sites of the two Fab fragments have been investigated by binding their appropriate haptens: vitamin K to Fab New (Amzel *et al*, *Proc natn Acad Sci USA*, **71**, 1427, 1974) and phosphorylcholine to Fab McPC 603 (Segal *et al*, *ibid*, **71**, 4298, 1974). In addition Edmundson, following his suggestion of the analogy of Bence-Jones proteins to Fab, has examined the binding of dinitrophenyl ligands to his protein (Edmundson *et al*, *Biochemistry*, **13**, 3816, 1974). In all cases binding takes place at a cavity between the variable domains, but the cavity has a different size and shape in the different molecules. Amzel *et al* describe their binding site as a shallow groove 15 Å × 6 Å × 6 Å while Segal *et al* find a large wedge-shaped cavity 12 Å × 15 Å × 20 Å and Edmundson a conical cavity 10 Å in diameter leading to a deep pocket. The groove or cavity is lined mainly or exclusively with residues from the hypervariable regions of the sequence, which in the structure cluster to form the surface of the binding pocket. Segal *et al* argue from their results that amino acid substitutions, deletions and additions in these regions could induce such differences in the overall shape, size and general chemical nature of the antigen binding sites that the hypervariability itself could be sufficient structural explanation for antibody diversity. On the other hand neither group working on the Fab fragments has observed any significant conformational change on hapten binding of the kind that might be expected to provide a structural basis for complement fixation or B-cell activation reactions (both functions of the Fc fragment). Nevertheless, Poljak *et al* do not rule out such a possibility and point to the asymmetric orientations of the switch regions as possible loci of structural alteration, which perhaps takes place when the true antigenic determinant rather than a simple hapten is bound.

THE continued existence of the apparently unstable West Antarctic Ice Sheet and Ross Ice Shelf is a major geophysical puzzle that only recently has been recognised. In this issue of *Nature* (page 168) Dr Gordon Robin presents new field data obtained on the Ross Ice Shelf and the very fast moving ice streams that drain the West Antarctic Ice Sheet. These field data are essential to the future solution of the puzzle.

The West Antarctic Ice Sheet forms one continuous body of ice with the Ross Ice Shelf. By definition the ice sheet becomes the ice shelf where the ice loses contact with bedrock and floats in sea water. The base of the West Antarctic Ice Sheet over much of its area is at the startling depth of 0.5 to 1 km below sea level. More over the bed would remain below sea level over a large area even if all the ice were removed and isostatic rebound took place. Only the great weight of the ice sheet keeps the ice pressed against bedrock. But at the edge of the ice sheet the ice thickness is insufficient to keep the ice mass grounded and here the floating ice shelf is formed. The ice thickness at the junction of the ice sheet and the ice shelf is greater than that of an equilibrium ice shelf that is nourished only by the snow that falls on it. Thus the Ross Ice Shelf becomes thinner the nearer it is to its seaward edge.

Stability of Antarctic ice

from J Weertman

It is natural to suspect that an ice sheet whose base is so far below sea level might be unstable. Hughes (*J geophys Res*, **78**, 7884, 1973) has suggested that the West Antarctic Ice Sheet is disintegrating. He thinks the junction of this ice sheet with the Ross Ice Shelf is retreating at present at a rate of about 70 m yr^{-1} . This rate of destruction of the ice sheet would raise the sea level by about 0.5 mm yr^{-1} .

On the basis of a simple-minded, two dimensional glacier mechanics analysis I found, essentially, that there is a 50-50 chance that the West Antarctic Ice Sheet is indeed disintegrating (*J Glaciol*, **13**, 3, 1974). A more accurate answer to the question of whether it is disintegrating and if so, how fast should be obtainable from a three dimensional glacier mechanics analysis carried out with the aid of computer calculations. Such an analysis requires the input of extensive field data from the West Antarctic Ice Sheet that have yet to be gathered as well as the field data that Robin has obtained for the Ross Ice Shelf. The question can, of course, be

answered with field observations. But it may be very difficult to determine where the Ross Ice Shelf joins the West Antarctic Ice Sheet if, as seems to be the case, there is no sharp line of demarcation. There seems to be a broad zone over which the ice alternately floats and is grounded. Furthermore, if the rate of retreat is of the order of Hughes's estimate, field measurements made over many decades would be required to obtain a reliable answer.

Robin's data on the ice streams may help solve another problem that could be related to the stability of the West Antarctic Ice Sheet and to which not even a tentative solution has been proposed in the literature: namely, why fast moving ice streams form near the edge of this ice sheet. Almost all of the ice that flows from the West Antarctic Ice Sheet moves through such streams which could be formed either in deep subglacial channels or because of an instability in the ice flow. There seems in fact to be no good field evidence that the ice streams are confined in deep channels in the bedrock. If the streams do not correspond to channels in bedrock their widths will be unstable and the West Antarctic Ice Sheet might surge by a rapid increase in the width of an ice stream. One theory of the ice ages is based on postulated surges of the Antarctic Ice Sheet.

Structure of a structural protein

from D L D Caspar

PROTEINS which build viruses, muscle, membranes and other cellular assemblies stand in a separate class from the soluble proteins of protoplasm and extracellular fluids. D A Marvin and his colleagues at Yale have now reported the construction of the first realistic molecular model of an assembly of a structural protein. The structure is a slender bacterial virus called Pf 1 which now becomes a robust paradigm for essential macromolecular assemblies in cells and tissue.

Marvin's quest for the structure of the filamentous bacterial viruses started a dozen years ago when these μm long, 60 Å diameter particles seemed a simple model system for defining the minimal properties of a self-assembling virus. His first X-ray patterns from fibres of the fd strain showed key features characteristic of α -helical fibrous proteins: strong diffraction near the equator at ~ 10 Å spacing and near the meridian on a ~ 5 Å layer line. Spectroscopic measurements indicated that the coat protein might be all α -helical in the intact particle, and the sequence of

the 50 residue fd subunit suggested which end would interact with the DNA core. Possible α -helical models for the subunit were built long before there was any clear idea of how to pack them in the virus particle. The problem was that the symmetry of the subunit packing was hidden in the X-ray pattern. Four other strains of this virus isolated in North America and Europe gave similarly inscrutable X-ray patterns. Attempts to figure out the coat protein design from misleading electron micrographs led to fanciful two-stranded models. Marvin, Wiseman and Wachtel (*J molec Biol*, **82**, 121, 1974) solved the packing problem by looking at the structure of two more filamentous viruses: Pf 1 isolated in Japan and Xf from China. These oriental strains gave readily scrutable X-ray patterns since they have regular helical symmetry (4.4 units per turn of 15 Å pitch). Moreover, the occidental strains could be seen by comparison to have similar underlying symmetry which was obscured by quasi-equivalent bonding of the subunits in a periodically

perturbed helix.

Marvin and Wachtel (*Nature*, **253**, 19, 1975) have gone on to solve the structure of the α -helical subunit in the oriental Pf 1 strain by first tracing out its backbone. This is defined by the near equatorial diffraction in the 10 Å region of the X-ray fibre diagram and by the rules for packing α helices in coiled coils which had been formulated by Crick in 1953. The α -helix axis is coiled into a segment of a left-handed conchospiral. This is the symmetrical curve on a conical surface which describes the form of conch shells and other growing helices. Each unit in the spirally thatched virus sheath interlocks over much of its length with the fifth and ninth units along the helix of 15 Å pitch. The side-chain packing cannot be seen from the X-ray pattern alone. Marvin's approach to this problem has been to fit the amino acid sequence of Pf 1 determined in collaboration with Nakashima, Wiseman and Konigsberg (*Nature*, **253**, 68, 1975) to the constraints set by the X-ray diagram and the stereochemistry. The acidic N-

terminus of the 46 residue molecule is placed outside and the basic groups near the C-terminus are arranged inside to neutralise the nucleic acid core. Following criteria worked out by Smillie and his colleagues (Hodges *et al*, *Cold Spring Harb Symp quant Biol*, **37**, 299, 1972) for "knobs-into-holes" interlocking of the tropomyosin side chains in a coiled-coil, the Pf 1 subunit can be arranged so that most of the hydrophobic residues make favourable van der Waals contacts with those on neighbouring α helices. It looks as if this ingenious model building from sequence data refined against a low-resolution X-ray fibre pattern may lead to as clear a picture of the atomic structure of this virus as protein crystallographers now produce by automated analysis of high resolution diffraction data from isomorphous crystals.

Structural molecular biology started with model building. Pauling and Corey discovered the α helix in 1951 by folding a stereochemically correct polypeptide chain to optimise the interactions between turns. Crick looked at the interactions between chains and constructed his models for α -helical coiled coils as well as his half of the double helix in 1953. Models of these helical molecules could be built and refined since the backbone folding was seen directly in the X-ray fibre diagrams. The chain folding in globular proteins is not, however, apparent from inspection of the forest of spots in single crystal diffraction patterns. Another breakthrough in 1953 was Perutz's introduction of the isomorphous replacement method which led the way for development of protein crystallography from what he called (in a different context) "the ingenious puzzle-solving of the early pioneers to the almost blindfold automation of the present day". The structures of many soluble globular proteins which yield excellent crystals have now been solved to atomic resolution by this technique. Crystallographic scrutiny has not been comparably successful with structural proteins since good crystals with small unit cells are uncommon—perhaps because these proteins are designed to aggregate in their own way. Isometric virus particles, enzyme complexes and other globular protein assemblies have been crystallised and these structures may be solved by crystallographic methods in spite of the very large unit cells. Structural proteins with recognisable backbones—such as tropomyosin filaments which give relatively poor crystals—will be solved like the filamentous phage by refining a molecular model against low resolution X-ray data.

The structure of a virus or a cellular assembly embodies the rules for its formation. The filamentous bacterio-

Visions of a laser accelerator

from O S Heavens

A LITTLE over twenty years ago, Smith and Purcell observed the emission of light from a metallised diffraction grating when a 300 keV beam of electrons was directed along the surface in a direction perpendicular to the rulings. This phenomenon, which is referred to as the Smith-Purcell effect, is easily understood in terms of the oscillations induced in the charge carriers in the grating consequent upon the passage of electrons close to the surface. Oscillations occur, minute dipoles are created, and for the appropriate choice of electron velocity the radiation emitted will lie in the visible spectrum. The effect has attracted a modest interest and several papers have appeared giving detailed theoretical accounts of the effect, which can be understood conveniently in terms of leaky space-charge waves from periodic structure, generally considered as alternately conducting and insulating strips.

Curiously enough, the emphasis has been entirely on the radiation produced by the interaction of the electron beam with the structure. The reverse effect—in which we ask what would happen to an electron beam near a periodic structure when an electromagnetic wave passes over the grating—seems not to have been considered until recently (Mizuno, Ono and Shimoe this issue of *Nature*, page 184). The intriguing possibility arises of using a coherent (laser) beam in such a way as to produce an accelerated beam of electrons. Accelerations of the order 1 GeV per metre seem to be feasible, coupled with the possibility of current pulses as short as 10^{-15} second, thus opening a new time domain to the experimentalist. It may be early to speculate that the typical large, expensive particle accelerator will become a white elephant, displaced by a laser of relatively trifling cost and an old diffraction grating. If this happens, and if laser fusion becomes a reality, optics may cease to be dismissed as an unfashionable old-hat topic neatly finished by one J C Maxwell!

phage is not constructed by simple self-assembly of coat protein and nucleic acid even though the design of the particle is determined by the specific bonding properties of its parts. A regulatory virus protein combines with the

viral DNA strand in the cytoplasm thereby segregating it from the replicating circular duplex and controlling its synthesis as a separate circle. The coat protein does not appear in a soluble form in the cytoplasm but is incorporated as it is made into the plasma membrane of the bacterium. Particle assembly proceeds by extrusion of the pre-packaged circular DNA molecule through the membrane bilayer where coat protein displaces regulatory protein. The assembly process is reversed in infection. Following attachment to a susceptible host by the A-protein located at one end of the virus filament the coat protein dissolves in the membrane bilayer as the DNA and A-protein are transported into the bacterium.

In the bacterial membrane, the virus coat protein may still be folded in its α -helical conformation stabilised by the oily environment, and it may span the bilayer with its positive and negative ends on opposite sides. This picture is reminiscent of many speculative models for membrane proteins—and one recent experimental one. Richard Henderson at the MRC laboratory in Cambridge has recently seen by X-ray diffraction that the purple membrane protein of *Halobacterium halobium* is folded into α -helical segments directed approximately normal to the plane of the bilayer and these segments appear to be packed together with coiled-coil interlocking (*J molec Biol*, in the press).

The filamentous bacteriophage in its different stages of development may be as useful for understanding membrane differentiation as it will be for comprehending fibrous protein organisation, regulation of DNA synthesis and control of virus assembly. Marvin has revealed this structure as a microcosm in which these basic problems in structural biology can be critically explored.

Molecular weight distribution in polymers

from Paul Calvert

GEL permeation chromatography (GPC) is the only satisfactory method of studying molecular weight distribution in synthetic polymers. Recent improvements in column packing materials and in molecular weight sensitive detectors should allow the development of this technique from a slow, poorly calibrated measurement into a rapid accurate one.

Synthetic polymers owe their utility to their high molecular weight, and average molecular weight is a much measured characteristic. But some important

properties are particularly sensitive to the molecular weight distribution as well as to the average for example a small fraction of very long molecules will markedly increase melt viscosity and a few short molecules can disproportionately reduce the breaking strength

Separation in GPC is due to differential exclusion of the randomly coiled macromolecules from pores in the particles of the column packing. Larger molecules are excluded from more pores and flow faster through the column. In operation the technique is clumsy. High temperatures are needed to keep many polymers in solution and this temperature must be closely controlled along 3–4 foot columns. High pumping pressures are needed but pressure variations must be minimised. The column packing may be cross-linked porous polystyrene particles, which are difficult to pack and use, or porous glass particles, but adsorption effects make such glass packings unsuitable for polar polymers. The eluting polymer is usually detected by differential refractive index measurement. A typical run takes 2–3 hours and a change of the solvent system is a major operation. Ideally, calibration would be performed using narrow molecular weight distribution polymers under the same conditions as the subsequent runs, but only for polystyrene are such fractions readily available. This problem is avoided by use of a universal calibration curve based on the assumption of separation by molecular volume and on known viscosity-molecular weight relationships for the polymer under run conditions. This calibration has often been questioned—for instance Otsuka and Hellman in *J Polymer Sci* (letters) (12, 331, 1974), show that it is successful for polystyrene on glass bead columns in a range of solvents but not on polystyrene-bead columns where the pore size is probably also a function of solvent.

Thus GPC is at present suitable for application where a large number of similar samples are to be measured but lacks the flexibility or accuracy necessary for research applications and is too slow for on-line process control.

Two papers by Ouano and Ouano and Kaye describe progress in the development of a molecular weight, continuous flow detector which would eliminate the calibration problem. The first (*J Polymer Sci* (A-1), 10, 2169, 1972) described the construction of a viscosity detector which measures the pressure drop in a capillary. Molecular weight could be determined to within 10% in a 10 μ l cell at concentrations of less than 10^{-1} g l $^{-1}$ and flow rates of 1 ml min $^{-1}$. The main drawback is the sensitivity to pump pulses.

A recent paper (*J Polymer Sci*

(Chemistry), 12, 1151, 1974) describes a low angle laser light scattering detector using a 6 μ l cell which will work at concentrations of 10^{-2} g l $^{-1}$, for molecular weights from 10^2 to 10^6 . Between the column and the cell a filter is necessary to remove fragments of column packing. The volume of the filter and its connecting tubing significantly reduces the resolution of the present system.

High speed GPC is a second recent development which is being studied in several laboratories. Unger *et al* (*J Chromat*, 99, 435, 1974) describe a system using polystyrene gel particles in which a 2 foot long column of 5 μ m particles could separate a polystyrene sample in 10 min, at a flow rate of 2.5 ml min $^{-1}$. Ultimately high speed must be at the cost of resolution but the use of small particles offsets this.

Radioactive tracers in the atmosphere

from D. H. Pearson

THE use of fission product pairs with similar half-lives as meteorological tracers is described in a recent paper (Holloway *et al*, *Journal of Geophysical Research*, 79, 4453, 1974). This is a recent example of the exploitation of radioactive tracers in the atmosphere, a technique that has developed considerably during the last twenty years.

The impetus came during the 1950s when it became necessary to determine the distribution of nuclear weapon debris by taking samples of airborne dust or rainwater and to attempt a quantitative estimate of the radioactivity in order to assess the radiological hazard. At first it was possible only to measure the gross radioactivity of the sample and then make corrections for decay, according to a crude assumption that the beta-radioactivity of the fission product mixture varied more or less inversely with time. Soon however the full sensitivity and resolution of the radioactive tracer method became available when samples of airborne dust and rainwater could be analysed for specific radionuclides.

The earliest and probably most rewarding achievement of this technique was the confirmation of the seasonal reinforcement of the troposphere in the early summer of each year by air from the stratosphere. The variation of the concentration of strontium-90 (half-life 28 year) in rainwater, and subsequently caesium-137 (30 year) in air, gave ample demonstration of the effect which had been previously indicated by the behaviour of ozone and water vapour in the atmosphere. At the same time it was possible to show that the radioactivity transferred from the stratosphere appeared in the troposphere with a maximum in mid-latitudes and minima at pole and equator.

The next advance in exploitation of the technique was to extract qualitative as well as quantitative information from these observations by measuring the radioactivity of

pairs of fission products. Thus the ratio of strontium-89 (50 day) to strontium-90, of cerium-144 (285 day) to caesium-137 and of various other combinations could be used to estimate the date of the fission explosion, or if the date was known then these ratios could indicate the proportion of nuclear debris released by the latest explosion against a background from earlier events.

Because the bulk of fission radioactivity has been inserted into the stratosphere it is possible to determine, by observations of these radioactive tracers, the delay of stratospheric residence time before the material returned to the surface of the Earth. The massive explosion series of 1961–62 were followed by several quiet years when it was possible to determine unambiguously a mean residence time in the (lower) stratosphere of about 16 months by measuring the decrement of the long-lived fission products strontium-90 and caesium-137. It was also possible to show, during this period when the northern hemisphere contained so much more fission radioactivity than the southern, that the mean residence time against interhemispheric transfer was between three and five years.

Meanwhile the radioactive tracer method has been used with natural radioactivity, derived both from the surface of the Earth and from cosmic radiation. Radon-222, emanating from terrestrial radium, has a succession of radioactive descendants, the longest-lived of which are lead-210 (22 year) and polonium-210 (140 day). These two tracers have been used, separately or relatively, as an index of the residence time in the troposphere, the resuspension of dust and the prevalence of continental or oceanic winds. A number of radioactive species are produced by the interaction of cosmic radiation with atmospheric nuclei. Of these, for example, the ratio of beryllium-7 (54 day) to phosphorus-32 (14 day) has been used to indicate vertical movements in the atmosphere.

These run times make possible process control using GPC

The availability of rapid, accurate GPC would be a great boost to polymer research, in studies of both polymerisation and polymer properties. Many effects which are attributed to changes in average molecular weight may turn out to be more directly related to changes in the distribution. In principle, these techniques would also extend the ability of porous gel (Sephadex) columns to separate complete mixtures of proteins, it will be interesting to see if they are taken up

Aerosol and climate: hotter or cooler?

by John Gribbin

THE puzzle of whether an increase in dust in the atmosphere leads to global cooling or global warming is given a further airing in a recent issue of *Science* (186, 827, 1974). According to some authorities this is a problem of extreme urgency, but the one sure conclusion from the latest results is that it cannot be solved by simple approximations

Just such a naive estimate led to the original fears that man-made aerosols (that is, small dust particles, not the gases used as propellants in so-called 'aerosol' sprays) might be blocking out enough of the Sun's heat to produce a significant cooling of the Earth, perhaps leading to a new ice age. Volcanic dust had already been suggested to contribute to the onset of natural ice ages, and experiencing a hazy day will suggest to most people that dust in the air reduces the temperature. Although such dust must prevent some of the incident radiation reaching the surface, however, the question remains of how much radiation is absorbed by the dust, and to what extent the dust prevents radiation from the Earth's surface escaping into space. These are non-trivial points, as calculations by Weare, Temkin and Snell emphasise. In simple terms, the problem

becomes one of whether the 'grey' particles of dust are distributed above a strongly reflecting 'white' ground surface, or above an absorbing 'black' surface. Earlier in 1974 Chýlek and Coakley reported calculations in which an analytical solution of the radiative transfer equation produces a guide to whether aerosol particles will lead to heating or cooling for any given albedo of the underlying surface. The critical ratio is that of the absorption cross section $(1-\omega)$ to the average back-scattering cross section $(\omega\beta)$ for the aerosol particles. When this exceeds a certain critical value, heating occurs, when it is less than that value there is cooling. And this critical value is related to the albedo of the underlying system (a) by $(1-\omega)/\omega\beta = (1-a)^2/2a$, where ω is the particle single scattering albedo (*Science*, 183, 75, 1974). This confirms that the same type of aerosol will have different effects over surfaces with different albedos and seemed to provide a guide to how these effects would vary. But the further study by Weare *et al* now shows the importance of at least one effect neglected in the earlier calculations.

This is the question of just where in the atmosphere the aerosol layer produces its greatest effect. The relation between aerosol properties and underlying albedo found by Chýlek and Coakley is restricted to the situation when the aerosol layer is distributed above the Earth-atmosphere system—and that is clearly a less than realistic situation. Numerical calculations for the cases when the aerosol layer is above or below the cloud layer, and for a "well mixed" model, show, not surprisingly perhaps, that "at any given preexisting Earth-atmosphere albedo, in order for added aerosol to result in heating, the critical absorption-to-backscatter ratio for the cloud is least when the aerosol is distributed above the cloud." For an annual global average albedo of 0.29, the critical ratio is 0.9 for an aerosol layer above the cloud, 1.3 in the well mixed model, and 3.2 for an aerosol layer between

the cloud and the Earth's surface

But even these calculations contain sweeping generalisations which require that they be used only with extreme caution in the real world. The "global average" approximation is itself an imperfect guide to reality, the calculations assume diffuse thin cloud rather than a 'lumpy' distribution of cloud cover, and aerosol particles from man's activities do not, by any means, cover the entire globe. The important conclusion from this work is that the effect of added aerosol on the radiation balance of the Earth does indeed depend both on the intrinsic optical properties of the aerosol particles and on their distribution through the atmosphere, as well as on the reflective properties of the underlying surface.

The situation also has an analogy in the problem of how aerosol particles might affect cloud cover. Acting as 'seeds' for droplet formation, they might increase cloud cover, increase the Earth's reflectivity, and produce a global cooling. On the other hand, if the particles simply attach themselves to existing droplets then 'dirty' clouds are produced, which could absorb more radiation and produce a global warming. It seems foolish for mankind to tamper with such a complex and ill understood system, and careless pollution of the atmosphere is unlikely to be a good thing. But we are still far from being able to say with confidence whether or not these polluting activities are hurrying the onset of the coming ice age.

Ocean-continent comparisons

from Peter J. Smith

THE idea has spread rapidly in the Earth sciences that some segments of continent are not truly continental at all, but are of oceanic origin. One of the best known examples of supposedly 'oceanic' continent is that of ophiolite sequences which are thought to be pieces of ancient ocean floor raised to the surface and sandwiched into continental material during the collision of tectonic plates. The importance of confirming such translocations can hardly be overemphasised, not only because of the plate tectonic implications but because it would mean that some oceanic rocks could be studied without the problems of accessibility posed by a thick cover of water. So although the evidence currently available is far from negligible, it is desirable that as many more ways as possible should be found to distinguish between oceanic and continental material. It is thus unfortunate that two potential geochemical differentiators have now proved to be unsuitable.

ANOTHER recent calculation of the effect of an aerosol layer on the heat balance of the Earth has been reported by Reck (*Science*, 186, 1034, 1974). She has looked particularly at the question of whether or not a balance between heating and cooling effects can be achieved, and finds that this is only so for underlying surface albedos in the range 0.35 to 0.60. For albedos greater than 0.60, the net effect is always a warming, for surface albedos less than 0.35 the net effect is always a cooling. This effect seems to be independent of the height of the

aerosol layer above the surface, but too much should not be read into the detailed results. As Reck stresses, the calculations assume average aerosol properties, an average underlying surface albedo, and take no account of the abundances and optical properties of water clouds. Nevertheless, they bear out results of similar but more complex earlier calculations (R. A. Reck, *Atmos. Environ.*, 8, 823, 1974). Reck therefore concludes that this simpler model "is sufficient to determine both the sign and the fact of a finite limit to the heating effect"

A hundred years ago

At the last meeting of the Photographic Society a paper was read by Mr Hooper, "On the Origin, Aim, and Achievements of the Photographic Society, with suggestions as to its future development." The suggestions were, the necessity of obtaining a Royal Charter, the Society's claim upon the Government for a money grant and suitable premises, and the necessity of forming committees for scientific investigation. In the subsequent discussion, the general opinion was that there was little hope of obtaining the proposed Charter, and that it was a mistake to speak of photography as a science. "Science," one speaker said, "had done a great deal more for photography than photography had done for science."

At the meeting of Convocation of the London University on Tuesday, the motion brought forward by Mr A P Hensman "That, in the opinion of Convocation, it is desirable that women should be permitted to take degrees in Arts in this University," was, after some discussion, withdrawn from *Nature*, 11, 236, January 21, 1875

The first such 'failure' arises incidentally from a study carried out by Schwarzer and Rogers (*Earth planet Sci Lett*, 23, 286, 1974). During their investigations of the geochemistry of flow and pyroclastic rocks in Texas, Schwarzer and Rogers decided to compare the major element chemistry of all the alkali olivine basalts they could find described in the literature. The data were subdivided into continental, oceanic and island-arc sets, according to the inferred crustal environment at the time the basalts were erupted, and plotted together on $\text{Na}_2\text{O} + \text{K}_2\text{O}/\text{SiO}_2$ and AMF diagrams. Neither the major element compositions nor the differentiation trends of the alkali olivine basalts varied significantly from environment to environment.

Schwarzer and Rogers conclude first, that alkali olivine basalt is a primary magma type generated worldwide, second, that the magma is generated at sufficient depth in the upper mantle that the crustal environment above (continent, ocean or island arc) has no influence on major element chemistry, and third, that the major element chemistry of the alkali olivine basalts that reach the surface is likewise unaffected by passage through crustal material. It is thus clear that the major element chemistry of alkali olivine basalts could not be used to differentiate ocean and continent

Mitchell and Aumento (*J geophys Res*, 71, 5529, 1974), unlike Schwarzer and Rogers, were explicitly seeking an ocean-continent differentiator (for ultramafic rocks)—and with some hope of success. Previous studies had suggested that the uranium content of primary minerals in oceanic ultramafic rocks may be quite different from that of the same minerals in continental ultramafic xenoliths. Aumento and Hyndman (*Earth planet Sci Lett*, 12, 373, 1971) found that the orthopyroxene in mid-Atlantic ridge ultramafics contains 1 p.p.m. of uranium on average, whereas clinopyroxene and fresh olivine poikilitically enclosed in chrome spinels contain 0.2 and 0.03 p.p.m. uranium, respectively. Kleeman *et al.* (*Earth planet Sci Lett*, 5, 449, 1969), on the other hand, found that in the ultramafic xenoliths from the newer volcanics of western Victoria, most of the uranium is in the clinopyroxenes (0.22 p.p.m.) and the accessory mineral apatite, whereas orthopyroxene, olivine and spinels contain very little (less than 0.0049 p.p.m.).

It is now clear that these differences, though real, are misleading. Mitchell and Aumento find that average uranium concentrations in orthopyroxenes in ultramafics from ophiolite sequences range from 0.02 to 0.072 p.p.m. Not only are these values much lower than those from mid-Atlantic ridge orthopyroxenes (0.75–1.20 p.p.m.), they are significantly lower than those in orthopyroxenes from (continental) kimberlites (0.11–0.88). On the other hand, they are higher than the values for (continental) Australian lherzolite (0.002). And although the uranium content of the orthopyroxenes in the mid-Atlantic ridge rocks is high, fresh orthopyroxenes in other oceanic ultramafics have very low uranium concentrations. Similar variations occur in the clinopyroxenes. Thus, for example, the uranium content of clinopyroxenes in ophiolites are comparable to those in coexisting orthopyroxenes, but much lower than those in clinopyroxenes in ultramafic rocks from either the mid-Atlantic ridge or cratonic continental environments.

Mitchell and Aumento go on to describe even more confusing variations, but enough has been said here to show that a simple distinction between oceanic and continental rocks on the basis of uranium content is out of the question for the time being. Part of the problem seems to be that considerable uranium enrichment takes place during processes of alteration. So although orthopyroxene in oceanic ultramafic rocks is the mineral most resistant to serpentinisation, and thus whose uranium content is most likely to resemble that of original fresh rock, some alteration may nevertheless have

taken place. For example, the mid-Atlantic rocks used by Mitchell and Aumento were from 45° N to 52° N and highly altered, and it is probable that the alteration has reached the orthopyroxene on a submicroscopic scale. Other mid-Atlantic (and mid-Indian Ocean) orthopyroxenes, reported by Seitz and Hart (*Earth planet Sci Lett*, 21, 97, 1973) do have uranium concentrations which are low and comparable to the corresponding values from ophiolites. It is possible, therefore, that more use may be made of oceanic uranium concentrations when the alteration processes are more fully understood.

The uranium variations within continental ultramafics may also be due in part to differential alteration, although some may arise from different modes of formation. Nishimura (*Chem Geol*, 10, 211, 1972), for example, has suggested that uranium content may vary with depth of origin. Again, a much more thorough knowledge of the processes involved will be required before uranium content can even be considered as an ocean-continent differentiator.

Theory of the nuclear optical potential

from P. E. Hodgson

ONE of the most basic interactions in nuclear physics is that between a nucleon and a nucleus. If we know this interaction we can calculate the cross section for elastic scattering and also the distortions of the nucleon waves by the nucleus which are essential for a thorough understanding of the reactions that can take place.

This interaction is really the sum of all the individual interactions between the incident nucleon and the nucleons of the target nucleus, modified by the correlation effects due to their proximity. As it is extremely complicated, many studies have been made to see how accurate it is to replace it by a simple one-body potential that takes no explicit account of the structure of the target nucleus. This potential has a radial shape very similar to that of the nucleus itself and has a real part and an imaginary part of which the former may be thought of as refracting the incident nucleons and the latter as absorbing them. The absorption takes account of all inelastic scattering and reaction processes that remove flux from the elastic channel. The one-body potential is called the optical potential because of the similarity between the scattering and absorption of nucleons by nuclei and the scattering and absorption of light by a refracting and absorbing medium. The former can be described by a complex potential and the latter by a complex refractive index.

This simple idea has proved astonishingly successful and it is now possible to account for the elastic scattering cross sections for many nuclei at many energies by suitably choosing the parameters of the potentials. It has been developed by the addition of a pin-orbit term, which allows the polarisation of the scattered nucleons to be calculated as well. The same potentials have been extensively used to generate the distorted waves needed in nuclear reaction calculations.

One of the main difficulties with these optical potentials is that they are frequently ambiguous; that is, it is possible to find several different potentials that give equally good fits to the experimental data. These ambiguities are much reduced as the precision of the data is improved, but some of them still remain.

Thus the purely phenomenological approach to the determination of the parameters of the optical potential, in which its parameters are systematically adjusted to optimise the fit to the experimental data, is inadequate. It needs to be supplemented by a more basic calculation of the potential from the constituent nucleon-nucleon interactions. Although this is very difficult and complicated, and many approximations have to be made in order to make the computations tractable, it is nevertheless able to give valuable information on the optical potential that substantially reduces the objectionable ambiguities.

The simplest of these calculations gives the real part of the optical potential as the folding of the nucleon-nucleon interaction $v(|\mathbf{r}-\mathbf{r}'|)$ with the nuclear density $\rho(\mathbf{r})$ where \mathbf{r} is the vector to the incident nucleon and \mathbf{r}' that to a nucleon in the target:

$$U(r) = \int v(|\mathbf{r}-\mathbf{r}'|) \rho(\mathbf{r}') d\mathbf{r}'$$

Many calculations using this approach, following the work of Greenless, Pyle and Tang (*Phys. Rev.*, **171**, 1115, 1968) have proved very successful.

The imaginary part of the potential is more difficult to calculate because in principle one should take account of all possible reaction processes, but some progress has been made by considering its strength as simply given by

$$W = \frac{1}{2} \hbar \nu \rho \bar{\sigma}$$

where ν is the velocity of the nucleon, ρ the nuclear density and $\bar{\sigma}$ the mean collision cross section. This relation follows from the semi-classical theory of the optical potential.

The success of these calculations has stimulated many more detailed theories of the optical potential. Among these some very successful calculations have recently been completed by Jenkne, Lejeune and Mahaux of the University of Liège (*Physical Review*, **C10**, 1391, 1974). In this work, the calculations were first of

Fig 1 Calculated strength of the real part of the optical potential as a function of incident nucleon energy compared with phenomenological potentials obtained from the cross sections for the elastic scattering of protons by ^{40}Ca and ^{58}Ni

all made for infinite nuclear matter, and then the results were applied to finite nuclei using the local energy approximation. This means that we solve the problem for infinite nuclear matter as a function of its density, and then apply the results to nuclei using their known density distributions. Thus the potential at a point of density ρ is assumed to be that given by calculations of the properties of infinite nuclear matter of density ρ . This approximation is justifiable if the nuclear density changes slowly over distances of the order of the mean free path of nucleons in nuclei, which is certainly true in the nuclear interior but is more questionable in the nuclear surface. The reason for making the first calculations in infinite nuclear matter is because there the nucleon wavefunctions are plane waves, which naturally simplifies the calculations.

The nuclear matter calculations were made by solving the Bethe-Goldstone equation, which describes the interaction of two nucleons inside the nucleus. To do this calculation we need to know the interaction between two nucleons in free space, and this is known quite well from many phenomenological analyses of the scattering of protons by protons and by neutrons at many energies. Of several forms now available the Reid potential was chosen as it has already been successfully used in a wide range of nuclear matter calculations. Inside the nucleus the nucleon-nucleon scattering is modified by the presence of the other nucleons and in particular many interactions are forbidden by the Pauli exclusion principle as

Fig 2 Calculated strength of the imaginary part of the optical potential as a function of incident nucleon energy compared with a number of phenomenological values

they proceed to states that are already occupied. This effect, incidentally, ensures that the mean free path of nucleons in nuclear matter is long enough for the shell model to be a valid description.

The solution of the Bethe-Goldstone equation and the extraction of the optical potential requires lengthy calculations, and some of the results are shown in the figures. Fig 1 shows the strength of the real part of the potential as a function of energy calculated for a Fermi momentum in nuclear matter of 1.40 fm^{-1} and taking account of the various terms in the mathematical expression for the potential. It is compared with phenomenological potentials obtained by analysing the elastic scattering of protons by ^{40}Ca and by ^{58}Ni . Up to about 100 MeV the radial dependence of the real potentials obtained in these calculations is very similar to the Saxon-Woods form:

$$f(r) = [1 + \exp\{(r-R)/a\}]^{-1}$$

used in most phenomenological analyses, but that at higher energies shows a pronounced surface peaking. Already some phenomenological indications favouring such a form have been found, and it will be important to take this into account in future analyses of the data.

The calculated energy variation of the strength of the imaginary part of the optical potential is compared with some phenomenological determinations in Fig 2. Its radial dependence changes from a predominantly surface-peaked form at the lower energies to a predominantly volume form at higher energies, and this is just the same behaviour as the phenomenological imaginary potentials. In phenomenological analyses there is much ambiguity between the amounts of volume and surface components, so that it is difficult to determine them individually. It will be a great advantage to have available some reliable theoretical guidance for the relative contributions of volume and surface absorption.

This work is in process of extension by taking into account some of the higher order terms in the solution of the Bethe-Goldstone equation, which should give improved optical potentials. Already the results obtained are most encouraging, in that they reproduce many of the features of the optical potentials already known from phenomenological analyses. As confidence in the reliability of such calculations grows, they will play an increasingly important part in guiding optical model analyses of elastic scattering cross sections. They should provide the essential behaviour of the form factors, leaving only the strength to be improved over the calculated values by optimisation of the fit to the experimental data. This should provide more reliable potentials that will improve the accuracy of the information on nuclear structure obtained from analyses of nuclear reactions.

review article

Chromosome imprinting and the mammalian X chromosome

H. Sharat Chandra

Microbiology and Pharmacology Laboratory and Centre for Theoretical Studies, Indian Institute of Science, Bangalore 560012

Spencer W. Brown

Department of Genetics, University of California, Berkeley, California 94720

Chromosome imprinting is the process by which one of two genetically homologous chromosomes is predetermined to function differently from the other at a subsequent stage in development. In the coccid insects, imprinting occurs in the egg, at the time of fertilisation, it probably occurs at the same time and site in mammals, and possibly also in Sciara

DURING development, a chromosome from the father may function quite differently from its maternal homologue, a fact discovered in the 1920s by Metz¹ in *Sciara*, a dipteran insect. According to his colleagues (C. Stern, personal communication), Metz often asked, "How do the chromosomes know which parent they come from?" Almost fifty years later, this question remains unanswered. Since then, the *Sciara* system has been explored in much greater detail, and systems of differential regulation of homologous chromosomes have been discovered in two additional groups of organisms. In the 1930s, the Schraders² analysed the chromosome system of the mealybugs and other coccid insects. In 1961, Lyon³ described the system in eutherian mammals, ten years later, a group of Australian workers^{4,5} reported a somewhat different situation in marsupials. It is the purpose of this account to outline similarities among these three systems and to show that analyses of such types of chromosome behaviour provide important clues to the nature of genetic regulation during early development.

Chromosome imprinting

Crouse⁶ introduced the term imprinting to indicate the process by which differential behaviour of the members of a pair of homologous chromosomes is predetermined several to many cell generations before the stage in development at which resulting behavioural differences become obvious. She provided an operational definition of imprinting, based on her work with *Sciara*, which should suffice until the imprinting mechanisms are more clearly understood. Confusion from use of the same term in behavioural sciences can be avoided in genetics by use of the complete term, chromosome imprinting.

It is not known how, in molecular terms, the differential chromosome behaviour originates, or, having arisen, is maintained in subsequent cell lineages, but some progress is being made in showing when and where the chromosomes are subject to imprinting. In her original definition, Crouse⁶ assumed that both paternal and maternal chromosomes carry an imprint. Imprinting of only one of two homologous chromosomes is, however, sufficient to account for differential behaviour and this simpler assumption will be followed here.

In the following sections, the systems involving differential behaviour of homologues will first be reviewed as a basis for understanding the evidence available from each on the process of imprinting.

Significant features of the three imprinting systems are compared in Table 1.

The system in mealybugs

Since mealybugs and certain related coccids provide unambiguous evidence of the site and time of imprinting, this system will be reviewed first. In males, the paternal set of chromosomes becomes heterochromatic during early embryogeny and remains so in most but not all tissues during subsequent development. Meiosis is highly modified and there is no recombination. At first division, both maternal and paternal chromosomes divide equationally. At second division, the paternal, heterochromatic chromosomes are segregated from the maternal, euchromatic chromosomes. Of the four products of meiosis, only the two euchromatic derivatives form sperm, the heterochromatic derivatives degenerate *in situ*. Such heterochromatization does not occur in females^{3,7}.

The genetic inertness of the paternal set has been demonstrated by several methods, including tests with genetic markers which are expressed in and transmitted by the sons only when received from their mothers⁸. Genetic activity of the paternal set is restored, however, in those tissues in which heterochromatization is reversed during development. There is thus a strict relationship between heterochromatization and the absence of detectable gene function. Heterochromatization of the paternal set is first detectable in male embryos at about the sixth cleavage when some nuclei migrate to the periphery of the egg. This is probably the stage at which gene action begins in the mealybug embryo as the incorporation of ³H-uridine by the chromosomes cannot be demonstrated earlier⁹.

Imprinting in mealybugs

Coccid chromosomes have a diffuse kinetochore and chromosome fragments function as independent entities. After maternal irradiation, euchromatic fragments appear in male embryos, after paternal irradiation, they are heterochromatic. Thus,

imprinting itself and the process responsible for its later expression as heterochromatization are effective along the length of the chromosome¹⁰. Somewhat similar evidence has been obtained from translocated chromosomes each carrying a euchromatic and a heterochromatic segment, these chromosomes behave normally until the second meiotic division when bridging results from movement of the euchromatic and heterochromatic segments to opposite poles^{11,12}.

Evidence on the place and time in development at which imprinting occurs comes from Nur's¹³⁻¹⁵ work with parthenogenetic soft scales, a group of coccids related to the mealybug. Two distinct types of parthenogenesis were found. In one type, the second polar body substituted for the sperm to produce a diploid 'zygote'. Heterochromatization was not found in any of the four species studied. In the other type of parthenogenesis, the egg nucleus divided to produce two haploid daughter nuclei which then fused to form a diploid, homozygous 'zygote'. This type of parthenogenesis was studied in three species. In two of them, both females and males were produced parthenogenetically (type A), the males were produced toward the end of the period of egg production and apparently never functioned because there were no sperm in the numerous females examined. In the third species, functional males were produced parthenogenetically and the females arose from fusion of eggs and sperm (type B). Heterochromatization in all three species was typical. One haploid set was heterochromatized and the other remained euchromatic. In these cases, therefore, imprinting must have occurred within the egg cytoplasm and it must have affected just one of the two haploid division products of the egg nucleus, presumably during the brief period the two haploid nuclei were separated from each other. In the species in which both males and females are produced parthenogenetically, genetic factors cannot be involved because the mothers also originate by fusion of two identical haploid sister nuclei and are therefore themselves completely homozygous. Since it is very unlikely that a new mechanism would have evolved to produce the unnecessary males in the type A parthenogenetic system, the situation in the sexually reproducing species must be the same, that is, the chromosomes of the sperm must be imprinted within the egg before fusion of egg and sperm pronuclei.

All sperm of a male mealybug carry identical, maternal chromosome sets, yet both sons and daughters result. In line with the conclusions from parthenogenetic soft scales, types A and B, male embryos are produced by eggs in which paternal chromosomes are imprinted and female embryos by eggs in which they are not. Two interpretations are possible. An imprinting region could be present in some eggs, absent in others, or the region could be variable in extent, sometimes large enough to affect the nucleus in question, sometimes not. The mealybug egg is spacious enough, 0.40 mm × 0.25 mm, to permit such internal differentiation.

When present, the imprinting region within the egg seems to be restricted. It clearly does not include the egg nucleus because the maternal chromosomes are not heterochromatized in the males of sexually reproducing species. The polar bodies also apparently escape imprinting. No males, nor any heterochromatization occurred in the four examples of parthenogenesis in the soft scales in which the second polar body substituted for the sperm. In the mealybugs, the polar bodies do not degenerate but give rise to certain polyploid tissues, heterochromatization does not occur in these complex cell lineages in either males or females⁷. Further evidence that mealybug polar bodies are not imprinted comes from crosses of heavily irradiated males and virgin females, the offspring are all gynogenetic females, and originate from one or both polar bodies. Such gynogenetic females can be triploid, diploid or mosaic, but their chromosomes are always euchromatic^{16,17}.

The system in *Sciara*

There is no differential heterochromatization in *Sciara* except briefly during development of the germ line, and the paternal chromosomes are genetically active¹⁸, but differential behaviour involves entire chromosome sets in *Sciara* as it does in the mealybug.

The *Sciara* zygote contains two sets of autosomes and three X chromosomes, two of which are of paternal origin. Its constitution can be symbolised $A^m A^p X^m X^p X^p$, in which m and p indicate maternal and paternal origin, respectively, of a set of autosomes (A) or an X chromosome (X). During embryogenesis, one X^p is lost from the germ line of both sexes and from the female soma, both X^p chromosomes are lost from the male soma. The resultant constitutions are: female and male germ line, female soma, $X^m X^p$, male soma, X^m only. The somatic constitutions are thus the conventional AAXX (♀) and AAXO (♂) even though the germ lines of both sexes are AAXX. Meiosis is atypical only in the male, at the first meiotic division, the paternal chromosomes are eliminated. During the second division, the two sister chromatids of the maternal X move precociously to one pole. A sperm is formed from the single meiotic product which contains the precocious X chromatids (now chromosomes), the other products degenerate. Because all sperm contain two X chromosomes, all zygotes contain three.

Imprinting in *Sciara*

Understanding of the *Sciara* system is simplified by the presence of two types of females: AAXX' which usually produce only daughters, and AAXX, which usually produce only sons. This feature simplifies the question of the localisation of imprinting. A single male can inseminate females of the two types, in the one, the chromosomes of the sperm are altered, in the other, they are not. Yet all sperm carry the same set of maternal chromosomes. Since the behaviour of the sperm

Table 1 Cytogenetic characteristics of the three imprinting systems

	Mealybugs and related coccids	<i>Sciara</i>	Marsupials	Mammals
Type of centromere	Diffuse	Localised	Localised	Localised
Sex chromosomes	None	Soma XX(♀)-XO(♂)	XX(♀)-XY(♂)	XX(♀)-XY(♂)
Differential behaviour occurs in	Male	Male	Female	Female
Chromosome imprinted	Entire paternal set	Entire paternal set but X differentially	X chromosome	Autosome*
Parental origin of imprinted chromosomes†	Paternal	Paternal	Paternal	Paternal autosome*
Heterochromatization	Yes	No	Yes	Yes (X chromosome)*
Genetic inactivation	Yes	No	Yes	Yes (X chromosome)*
Site of heterochromatization	Germ line and soma		Soma only	Soma only
Reversal of heterochromatization may occur in	Soma		Not detected	Not detected
Meiosis	Paternal set eliminated	Paternal set eliminated	Typical	Typical

*Proposed model: an autosome is primarily affected, the X chromosome secondarily, see text.

†In typical bisexual reproduction, see text for parthenogenetic examples.

nucleus is determined by the type of egg it enters, the evidence that the fate of the paternal chromosomes is determined within the egg is incontrovertible. If imprinting does not occur within the egg but rather in the body of the father, eggs of AAXX' females must be able either to erase the imprinting or fail to facilitate its expression. The kinds of parthenogenesis seen in coccids which could provide definitive evidence that the egg is the site of imprinting have not so far been observed in *Sciara*.

By appropriately manipulating the chromosomes, *Sciara* can be induced to produce exceptional offspring, sons from AAXX' mothers, and daughters from AAXX mothers^{19, 20}. Since such exceptional offspring have the somatic chromosome complement expected of their sexes, it follows that sex is determined by the chromosomes. The genetic constitution of the mother determines only the chromosome eliminations which will occur and does not influence the sex of the offspring. The exceptional males arising from AAXX' mothers are, however, sterile, probably because their germ line constitution is AAXO rather than the normal AAXX²⁰.

The special behaviour of the *Sciara* X chromosome is determined by a controlling element located close to the centromere⁶. This controlling element is probably altered during the second meiotic division so that one of the then sister chromatids can later respond differently either to imprinting or to the later influences responsible for its expression.

In X-autosome translocations, the derivative carrying the X centromere conforms to the X-chromosome type of behaviour in its manoeuvres during development. It is reasonable to assume, therefore, that imprinting in *Sciara* need occur only at or near the centromeres.

The system in mammals

As is well known from confirmations of the hypothesis proposed by Lyon³, only one of the two X chromosomes is genetically active in somatic cells of female mammals. During early embryogeny of eutherian mammals, the active X is chosen at random and could be either maternal or paternal in each cell. In contrast, in marsupials it is the maternal X that is active and the paternal X is inactive or largely so^{4, 5, 21}. In both cases, inactivation of one X chromosome in the female serves as a dosage compensation mechanism by equating the single active X of the XX female with the single active X of the XY male. In both sexes there is the same balance between one functional X chromosome and two sets of autosomes. Selection for genes capable of functioning adequately in this situation offers a possible explanation^{22, 23} for the relative evolutionary constancy of the mammalian X in regard to both size and content²⁴. The eutherian system is selectively advantageous because random inactivation confers a 'mosaic heterozygosity' which is not possible in the marsupial system²⁵. Indeed, the apparently large effect of heterozygosity for human X-linked genes may result from mosaic heterozygosity²⁶.

The eutherian system can be derived from the marsupial system by a single mutational step²⁵. According to this scheme, the marsupial X carries a sensitive site and a receptor site adjacent to it. Imprinting of the sensitive site on the X chromosome brought in by the sperm leads to the inactivation of the site. The sensitive site on the X chromosome contributed by the egg is not so imprinted, it remains active and produces an 'informational entity' which attaches to the adjacent receptor site. At a later stage in embryogeny, the X without the informational entity (that from the sperm) becomes heterochromatic and genetically inactive, the X with the attached entity (that from the egg) remains euchromatic and active or potentially active.

To obtain the eutherian system, it is necessary to assume that during evolution a translocation moved the sensitive site from the X chromosome to an autosome and that the receptor site continued to remain on the X chromosome. Since the sensitive site is dissociated from the receptor site, the informational entity produced by the maternally-derived sensitive site would attach at random to the receptor site of either the paternal

or the maternal X chromosome. Translocation of the sensitive site to an autosome is thus the only step necessary to change the marsupial to the eutherian mode of regulation. As a consequence, in eutherians, the number of active X chromosomes would be the same as the number of maternal chromosome sets except when there is monosomy or trisomy for the autosome carrying the sensitive site²⁵.

Imprinting in mammals

What little evidence there is on site of imprinting in mammals comes from human ovarian teratomas^{27, 28} and a human diploid/triploid mosaic^{29, 30} (Fig. 1). Ovarian teratomas are usually benign tumours which resemble sexually produced embryos in that they often contain tissues such as hair and teeth. Their chromosome constitution, 46XX, is normal. No genetic markers are present in the teratomas other than those in the woman. The fact that some maternal markers are missing, however, indicates that teratomas are postmeiotic products of maternal origin. The most plausible interpretation of these data is that the abortive development culminating in a teratoma is the result of "re-entry" of the second polar body (PB2) and its subsequent fusion with the egg²⁸.

Fig. 1 Presumptive origin of human ovarian teratomas^{27, 28} (left) and a human diploid/triploid mosaic female^{29, 30} (right) and interpretation of their sex chromatin status²⁴. Stippled areas denote the regions in which imprinting would occur. A and X denote, respectively, an autosomal set and an X chromosome, superscript p indicates paternal origin and m, maternal origin, subscripts PB and E refer to polar body and egg, respectively. n, 2n, 3n denote haploid, diploid and triploid nuclei, respectively. Asterisks indicate the imprinted chromosome sets. In the teratomas, the sensitive site of one of the two haploid maternal nuclei (that from polar body II) is assumed to be imprinted, resulting in one X being active and the other inactive. Similarly, in the mosaic female, imprinting of the second maternal nucleus (again from polar body II) in the triploid cells would explain the fact that, contrary to expectation (see text), two sex chromatin bodies were found in her triploid cells.

Since the teratomas have two maternal sets of autosomes, they would, on the basis of the proposed model of regulation, be expected to have both X chromosomes active, but in fact, one X chromosome was found to be inactive (sex chromatin)^{27, 28}. The presence of an inactive X in these teratomas provides the most convincing evidence yet that the factors regulating X chromosome inactivation can be exclusively maternal in origin²³.

In the diploid/triploid (46XX/69XXX) mosaic^{29, 30}, the extra set of chromosomes was maternal in origin, but whether it was genetically identical to the maternal set in the diploid tissues is not known. The simplest explanation for the origin of the mosaicism is, again, that the haploid PB2 re-entered and fused with one of the early cleavage nuclei (diploid) to form the triploid tissues. As in normal females, a single sex chromatin body was seen in diploid cells, but two were seen in triploid cells³⁰ although two autosomal sets of maternal origin would lead to an expectation of two active and one inactive X chromosomes²⁵.

Contrary to these expectations, two maternally derived chromosome sets were associated with an inactive X in both teratomas and in the triploid tissues of the mosaic girl. In both cases, however, one of the two maternal complements was probably provided by the second polar body. It is also significant that as in the parthenogenetic soft scales (above, types A and B), the two maternal complements were presumably separated from each other before fusion. If the assumption is made that one of the two maternal complements (polar body II) was imprinted during the period of separation, then these exceptional data would no longer be inconsistent with the model²³. If, on the other hand, the maternal contribution to the individual is in the form of a single egg nucleus, then the number of active X chromosomes is the same as the number of maternal autosomal sets—whether the egg is haploid, diploid (for example because of suppression of the second meiotic division by colchicine²¹), or aneuploid for the sex chromosomes²⁵. The simplest interpretation of the mammalian data is that the imprinting zone includes all or nearly all of the periphery of the egg²³.

In three other digynic triploid/diploid mosaics (see ref. 33), both Xs of the XXY or XXYY triploid sectors were active, thus indicating that the second maternal contribution could not have been imprinted. Differences in imprinting of the maternal genome may stem from the variable behaviour of PB2, in mice PB2 may either be extruded or retained in the egg proper to form a second female pronucleus³³. In its usual place, PB2 would be subject to imprinting and, on re-entry, would provide the stimulus necessary to initiate a teratoma²⁸. If retained within the egg proper, PB2 would be imprinted only if it came in contact with the periphery of the egg before fusing with a cleavage nucleus to initiate the triploid cell lineage. PB2 has never been observed to undergo division in mammals³³, evidence for its fusion comes solely from teratomas and mosaics of the type considered here.

It therefore seems that polar bodies of mammals, but not those of coccids, may be subject to imprinting. Furthermore, determination of sex in mealybugs is by imprinting (or the two events are at least coupled) so that capacity to imprint must be variable enough to permit production of both sexes. In mammals, on the other hand, sex is determined by the chromosomes, and X chromosome behaviour proceeds according to schedule regardless of sex of the embryo, there is a single active X in both XY and XXY males²⁵.

In conclusion, (a) the egg is the site of imprinting, almost certainly in mealybugs, probably in mammals, and possibly in *Sciara*, (b) imprinting of sperm seems to be a variable process within the eggs of mealybugs and related coccids and a consistent process within mammalian eggs, (c) if two maternal chromosome sets in mammalian eggs fuse after prior separation, one may become imprinted, and (d) in both coccids and mammals there is no necessity for assuming, as may be necessary for *Sciara*, a second level of control to explain the data.

Finally, in all three genetic systems, entire chromosomes are subject to differential regulation even though only one or a few loci may be responsible for initiating differential behaviour. Immunoglobulins represent the only other case known in which homologous genetic loci function differently within a single cell³⁴. Whether this unusual behaviour—believed to be related to the function of immunoglobulins—is also based on mechanisms analogous to imprinting is not known.

Ice shelves and ice flow

G. de Q. Robin

Scott Polar Research Institute, Cambridge, UK

New data on the Ross Ice Shelf provide an insight into the importance of the momentum with which an ice stream enters the shelf for the overall velocity field

Of the 13,800,000 km² of ice covering Antarctica, some 12,100,000 km² lie on a rock base, while about 1,500,000 km²

are in the form of floating slabs of ice round the periphery of the continent. The largest of these is the Ross Ice Shelf. In contrast to the inland ice, which built up into a vast relatively flat dome until surface slopes and ice thickness produced sufficient gravitational forces to drive ice outwards against frictional drag at the base of the ice, the floating ice shelves rest effectively on a frictionless base. The first theoretical ideas

treated ice shelves as flat plane parallel slabs of ice spreading under their own weight^{1,2}, but observations³ soon showed that ice shelves slowly increase in thickness as one moves in from the seaward boundary, known as the ice front. This thickening was satisfactorily explained in terms of drag, mainly on the sides of the ice shelves, but also by local grounding⁴⁻⁶. No theoretical studies or relevant field observations were, however, made of the corresponding problem of faster moving streams of ice within an ice shelf. This problem will now receive considerable attention as the various studies of the Ross Ice Shelf Project (RISP) develop.

The observations

To provide the first data for planning this programme, extensive airborne soundings of the ice shelf were made between

1967 and 1972. These are presented in this paper. On the basis of (a) these new measurements of ice thickness, (b) earlier measurements of velocity, and (c) the assumption of mass continuity, it is possible to estimate the direction and speed of ice flow over the entire shelf. These predictions will be tested by direct measurements of flow velocity as the Ross Ice Shelf Geophysical and Glaciological Survey operations are continued during the present Antarctic summer and the years following, as part of the RISP.

The new map of the thickness of the Ross Ice Shelf (Fig 1) is based on profiling of ice thickness by radio echo sounding from aircraft. The thin, approximately straight lines on the map show aircraft flight lines along which continuous profiles of thickness are available. These total some 35,000 km of track as compared with about 3,000 km which had been

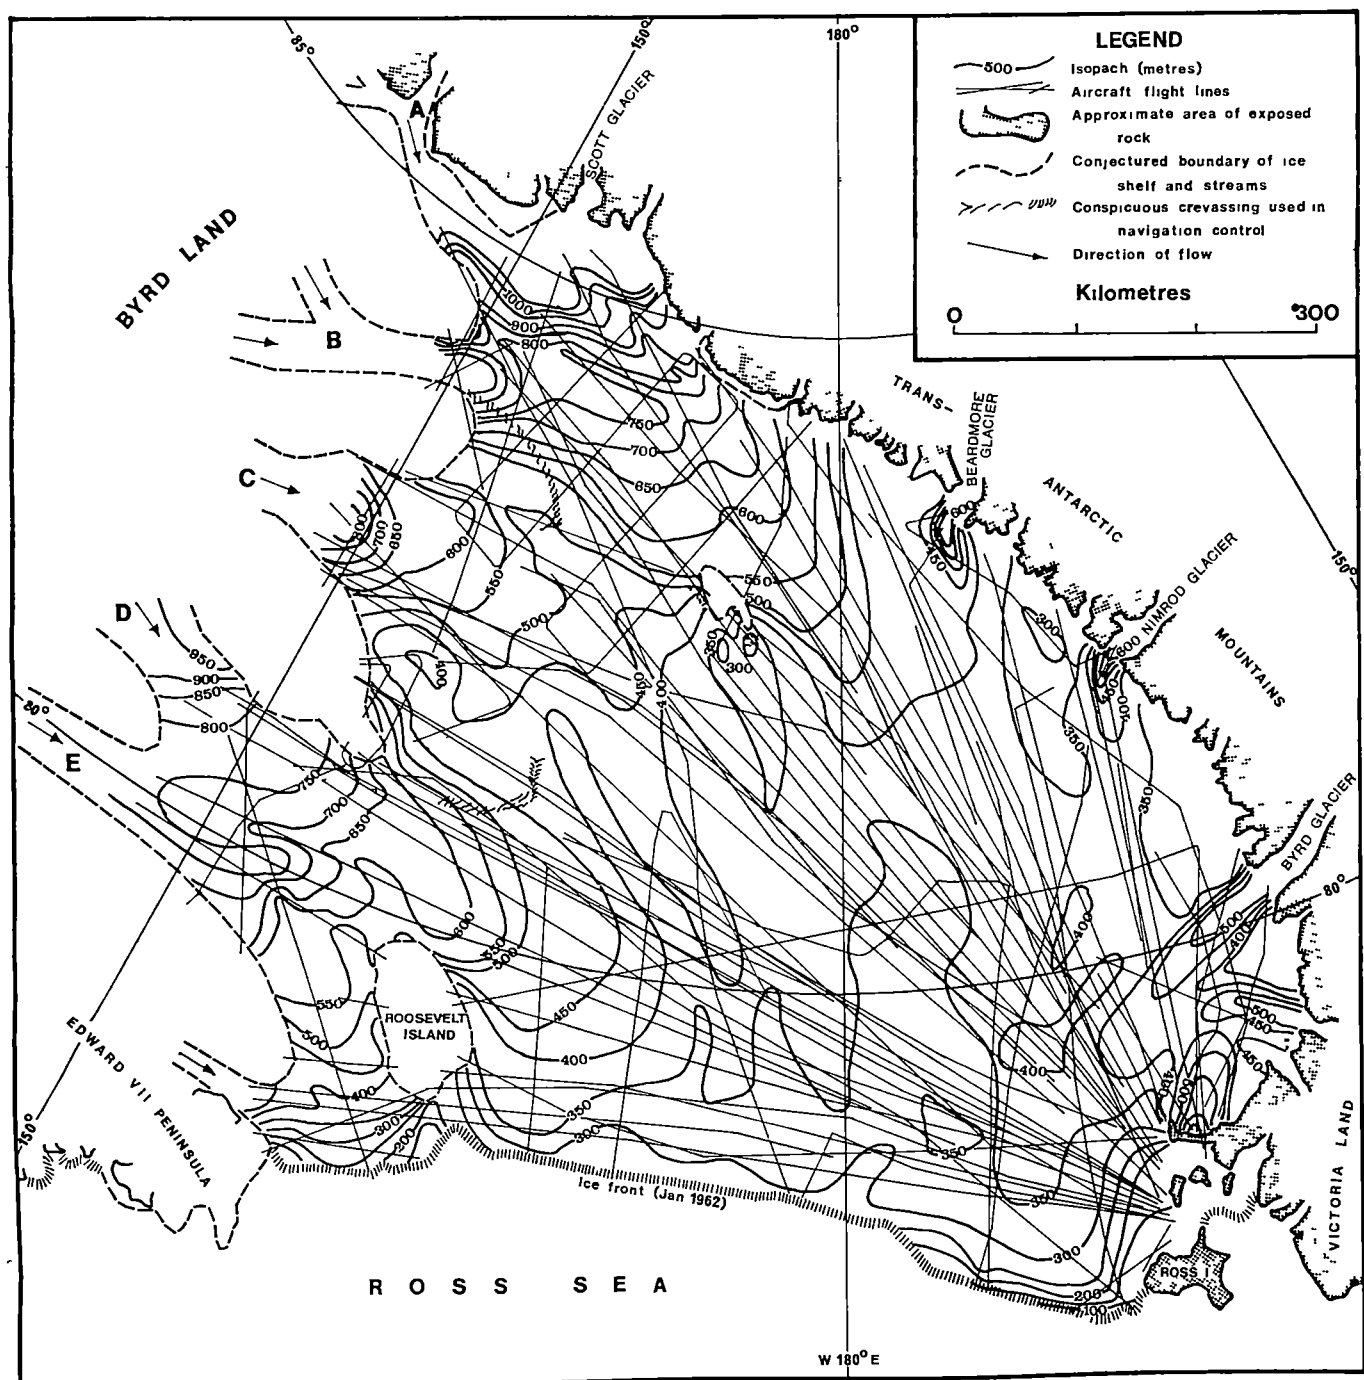

Fig. 1 Flight lines on which data were gathered

measured previously by other methods (some 50 seismic soundings plus levelling along surface traverses). The data presented in this paper were obtained as part of the joint Scott Polar Research Institute-US National Science Foundation programme of sounding the Antarctic ice sheet from long range aircraft of the US Navy experimental squadron VXE6.

Two networks of flight lines are shown on the map because some of the flights combined logistic and research tasks. Lines which are approximately radial from the southern end of Ross Island are from flights which were made to sound more distant areas or to supply fuel to Byrd station or the South Pole; lines that cut across the radial pattern are from flights flown specifically for sounding the Ross Ice Shelf.

The importance of this new information is the clearly marked distribution of ice thickness. It can be seen, for example, that the major glaciers entering the ice shelf persist for some distance as streams of thicker ice within the shelf. The possibility of deducing patterns of ice flow from distribution of thickness offers a new tool of considerable importance in the study of the flow and deformation of ice shelves.

Accuracy of the data

Before discussing the implications of the new data, we must first consider the accuracy of measurements and the related problem of aircraft navigation. The general technique of radio echo sounding has been discussed in detail elsewhere⁷⁻¹⁰. When sounding ice shelves, as distinct from inland ice, the strength of the bottom echo is generally sufficient to permit soundings from aircraft flying at their economical cruising altitude of from 7,000 to 10,000 m, as opposed to the lower altitudes necessary for sounding of inland ice. A time delay on the oscilloscope trigger, plus an appropriate sweep speed, was used to spread the echoes from top to bottom of the ice shelf over a substantial portion of the oscilloscope screen, and hence of the recording film. Under these circumstances, errors of measurement of ice thickness are of the order of 10 m, of which 4 m are due to scaling off the film record and about 1.5% due to uncertainty over the velocity of radio waves in ice and firm.

An overall test of accuracy comes from comparison of thicknesses interpolated from Fig. 1 with those at 44 locations measured by seismic sounding¹¹. The arithmetical mean difference with regard to sign was only 4 m, the radio echo depths being the greater. The root mean square deviation between the two sets of measurements was 25 m and the maximum difference 67 m. These results indicate that the main sources of error probably come from errors of navigation and interpolation, since both are likely to produce random errors which will cancel out when averaged over many observations. The remaining difference of 4 m between the two systems is not significant.

Navigation was the chief difficulty. Most of the flight lines in Fig. 1 were flown during the 1969-70 season in a C130 (Hercules) aircraft at 7,000 to 10,000 m. Conventional navigation methods (TACAN, Sun shots, radar fixes, air photographs when within 150 m of mountains) were used. Although errors of up to 50 km may be expected, careful navigation by the aircrew, subsequent checking of interpolated (dead reckoning) positions and the relatively slow variation of wind speed and direction in the upper troposphere in summer, all served to limit errors. After some flight lines were rejected because of inconsistencies of navigation, the selected lines were plotted in a series of colours along each line, each segment of colour corresponding to a given 50 m range of depths. Then, since the remaining navigational errors were not large, a clear pattern of colour emerged on which isopachs (lines of equal thickness) could be drawn with confidence. Variations of thickness between different flight lines indicate that naviga-

tional errors were generally less than 16 km. Where there was a high density of flight lines, averaging of navigational errors should reduce errors in the position of isopachs to 10 km or less.

In 1971-72, inertial navigation (Litton 51 C) fitted to the aircraft gave a continuous record of position to an accuracy of better than 5 km for two flights that were made partly over the ice shelf. On one of these flights, four parallel lines that were flown over the south-eastern corner of the ice shelf did much to resolve the detailed pattern of thickness, and subsequently of ice flow, in this key area.

Results of four flights in 1967 by C131 J (Super Constellation) aircraft are also included. These were made at lower levels (1,000 to 2,000 m) where winds are more variable and navigational errors greater. The flight paths have been adjusted to match the thickness data from these flights to those obtained during the 1969-70 season.

Thickness pattern and streamlines of flow

Figure 1 shows the extent to which glaciers persist as streams of thicker ice within the shelf. The same effect is seen in relation to the streaming of thinner ice, especially downstream of the small ice rise around 83°S, 172°W. It is possible that the thinner stream of ice starting around 82°S, 164°W may also be caused by local grounding in this area, even though no ice rise is present. Alternatively this thinner stream may be the result of shear between ice streams moving at different speeds. Similar thinning is seen around 84.5°S, 155°W between ice streams A and B and between ice streams D and E around 80.2°S, 155°W.

In the central part of the ice shelf, where the ice shelf varies slowly between 450 and 300 m in thickness, the isopachs are less accurate, and it is more difficult to deduce streamlines. The isopachs in this area represent mean values from a number of flight lines, especially for the closed isopachs for 350 and 400 m between 170°E and 180° in which most but not all ice thicknesses exceed the indicated values. Near the ice front the effects of bottom melting appear to dominate the thickness pattern, especially in the vicinity of Ross Island, where rapid melting has been shown to take place^{11,12}.

It is clear that in order to deduce directions of ice flow, we must use these indications of streaming, rather than attempt to use mean surface slopes as is done in the study of inland ice. (In the case of floating ice shelves, surface slopes are proportional to thickness gradients.) Nevertheless, there is a general decrease of ice thickness as one moves along individual flowlines towards the ice front, and even in the few areas in which the ice thickness does increase towards the ice front, the rate of increase is slow and is probably due to new accumulation along the line of flow rather than compression of ice in this direction. Indeed there is little evidence from the map that compression along a flowline can take place, although compression occurs normal to flowlines over much of the ice shelf. This agrees with the concept that ice shelves spread out under their own weight while floating on a frictionless base^{1,2}.

The increasing thickness of ice shelves with distance from the ice front, which is explained by drag at the lateral boundaries of the shelves, has a counterpart in individual ice streams within an ice shelf. When a rapidly moving stream enters the shelf, it will be retarded by the slowly moving ice on either side, with the result that its thickness increases in the upstream direction. But in the ice to either side the opposite effect takes place, the rapidly moving ice stream drags the surrounding ice forward, causing a thinning as one moves upstream. This is particularly noticeable between Beardmore, Nimrod and Byrd Glaciers. We will consider this point later in more detail.

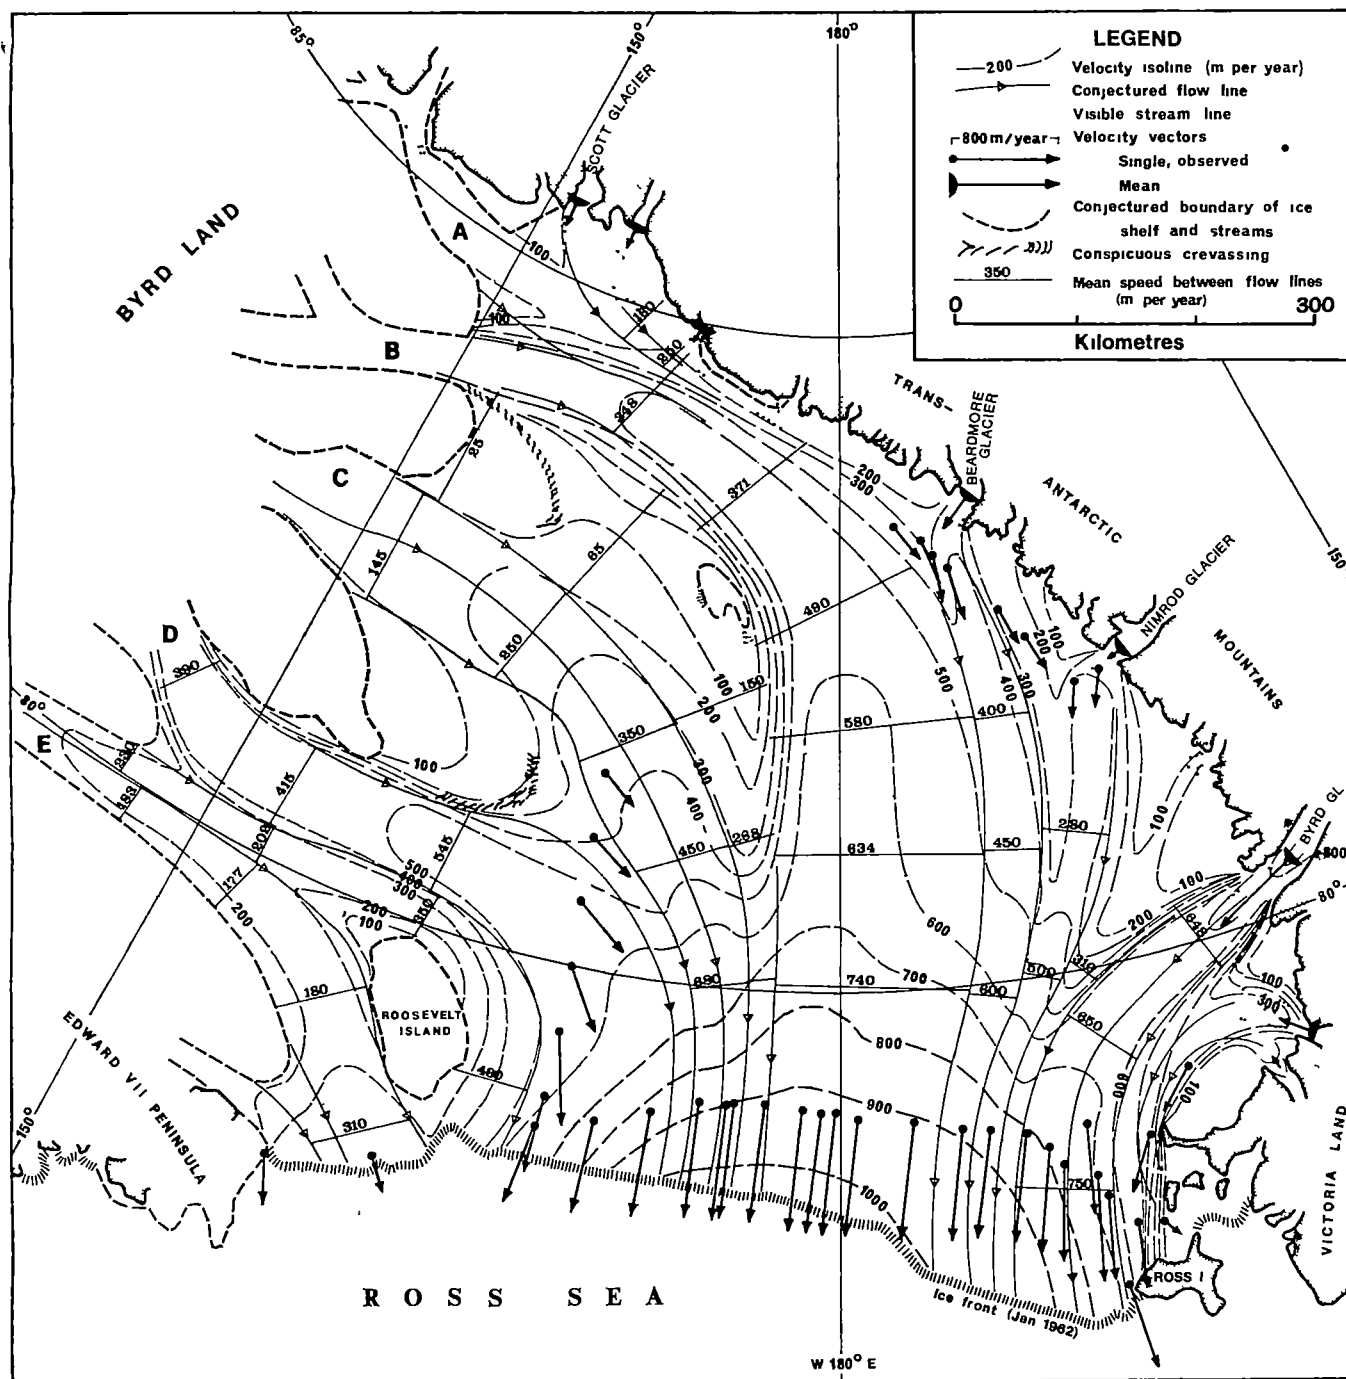

Fig. 2 Velocity field of ice flow

Velocity distribution within the Ross Ice Shelf

Figure 2 shows the speed and direction of movement over the Ross Ice Shelf. Vector arrows show direct measurements of movement made by earlier investigators¹⁴⁻¹⁶. Streamlines of ice flow deduced from the thickness pattern and from calculations are shown by continuous lines, while dashed lines indicate lines of equal speed. Between 180° and 150°W streamlines were deduced entirely from the thickness pattern, and their direction agrees well with the direct observations of movement along 164°W.

We have assumed mass continuity of flow to extrapolate velocities upstream from Dorrer's velocities along 79°S (ref. 16). If \bar{V}_1 is the known mean velocity along a line 1 be-

tween two flowlines, the mean velocity \bar{V}_2 along line 2 between the same flowlines at a distance δx upstream is given by

$$\bar{V}_2 = \bar{V}_1 \frac{\bar{H}_1 W_1}{\bar{H}_2 W_2} - \bar{B} \frac{\delta x}{\bar{H}_2} \left(\frac{W_2 + W_1}{2 W_2} \right) \quad (1)$$

where \bar{H}_1 and \bar{H}_2 are the mean ice thicknesses and W_1 and W_2 the widths between the flowlines along the lines 1 and 2, and \bar{B} is the mean mass balance per unit area over the area bounded by lines 1 and 2 and the flowlines. This mass balance must take account of accumulation and ablation on both upper and lower surfaces of the ice shelf. Observations by Cray and coworkers¹¹ show the distribution of net annual accumulation on the upper surface of the ice shelf, which

varies from 0.16 to 0.30 m yr⁻¹ of ice. We know that bottom melting up to at least 0.50 m yr⁻¹ occurs near the ice front while freezing may take place under the southern part. We assumed bottom melting of 0.12 m yr⁻¹ between 79°S and 80°S, falling off to zero between 83°S and 84°S, and we have made no allowance for any bottom freezing. The resultant mean velocities (m yr⁻¹) are shown in Fig. 2 above the lines to which they apply.

Although streamlines could readily be deduced from the thickness of the ice on the shelf between 150°W and 180°, between 180° and 160°E their location was less clear. In this section, flowline positions were adjusted through a process of iteration until calculated velocities near the Beardmore, Nimrod and Byrd Glaciers matched the observations.

The velocities between the pair of flowlines finishing either side of the 180° meridian are worthy of particular attention. Once the streamline flow in the south-eastern corner of the ice shelf had been determined by the 1971–72 flights with inertial navigation, it was clear that the major discharge of ice stream B passed to the south of the ice rise at 83°S, 172°W. As we knew the mass discharge of the Robert Scott Glacier and the Amundsen Glacier to the west, and could identify their flowlines to 165°W, we estimated the mean velocity of their stream at this point as 250 m yr⁻¹ compared with a mean value over the line also including the discharge of stream B of 348 m yr⁻¹. The velocity of the latter must therefore be around 500 m yr⁻¹. This result is particularly interesting for it explains why the rapid discharge of the stream B, which is only 800 m thick where it enters the ice shelf, dominates and rapidly bends the flow from the Robert Scott and neighbouring glaciers, although they are several hundred metres thicker on entering the ice shelf. In this area where there are strong thickness gradients, and hence greater surface slopes than elsewhere, we see that the slopes do not govern the movement. This is controlled mainly by the momentum of the stream with the largest mass discharge into the ice shelf.

Although a fully satisfactory three-dimensional solution to the problem of deformation within ice shelves has not yet been given, some relevant factors can be appreciated by considering the equations for quasi-static creep of an ice shelf. We take the x axis to be oriented in the direction of flow and the z axis vertical. Then provided we are clear of local boundary effects and have no friction on upper or lower surfaces, we assume the shear stresses in the xz and yz planes to be zero, so the basic equilibrium equations⁶ reduce to

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} = 0 \quad (2)$$

$$\frac{\partial \sigma_y}{\partial y} + \frac{\partial \tau_{xy}}{\partial x} = 0 \quad (3)$$

$$\frac{\partial \sigma_z}{\partial z} = \rho_i g \quad (4)$$

where ρ_i is the density of ice and g the gravitational force. The earliest theories of the flow of ice shelves^{1,2} were based on (4), while solutions including the effect of lateral drag either used the simplifying assumption⁵ that $\partial \tau_{xy}/\partial x = 0$, or⁶ that $\partial \tau_{xy}/\partial x$ was constant. We can see from equation (2) that as an ice stream is slowed down as it moves out into a uniform ice shelf, the change of stress in the direction of flow, and hence by simple theory of the ice thickness, must be balanced by a gradient of shear stress in the normal direction.

Similarly, any horizontal stress gradient normal to the flowline, which we expect to be present if the thickness varies across an ice stream, must be balanced by a gradient of shear stress in the flow direction.

We can summarise the position by saying that if an ice shelf is of uniform thickness, no differential stresses $\partial \sigma_x/\partial x$, $\partial \sigma_y/\partial y$, $\partial \tau_{xy}/\partial x$, $\partial \tau_{xy}/\partial y$ will be present. If the thickness varies in the flow direction, but is constant in a direction normal to flow, then $\partial \sigma_x/\partial x$ and $\partial \tau_{xy}/\partial x$ are not zero, and approximate solutions^{5,6} apply. But we must take account of all the four stress gradients if we are to obtain a solution to the problem of differential flow within an ice shelf.

Our results show that the largest thickness gradients occur normally to the flow direction on the sides of the major ice streams, and hence it seems that our maximum horizontal stress gradients $\partial \sigma_y/\partial y$ also occur here. From equation (3) we see also that the expected maximum values of $\partial \tau_{xy}/\partial x$ are in these regions. This fits the physical picture that the drag on the sides of an ice stream should vary most rapidly near its entry to the ice shelf. Although we cannot give a full solution, we see that as the shear gradually disappears as one moves further into the ice shelf, the thickness of the shelf becomes more uniform. Then, if we neglect other factors such as bottom melting and drag at the boundary of the ice shelf, we expect that as the ice stream approaches the same thickness as the ice shelf on either side, differential motion within the shelf will become small.

Our results indicate that the momentum with which an ice stream enters the ice shelf is perhaps more important than expected. The same process, but in an inverse sense, appears to explain the thicker ice to the south of Minna Bluff, the promontory that juts out into the ice shelf around 79°S to the south of Ross Island. But in this case it is the ice shelf streaming past the promontory that seems to provide the force that, rather than lateral drag, causes thickening in this area. The most complex situation is that caused by different ice streams entering the south-eastern corner of the ice shelf from different directions and at different speeds. Clearly a full solution for this case, both analytically and in terms of gathering adequate field data on all boundary conditions will be difficult. Similar considerations also apply near the ice front where the mechanics of calving of large tabular icebergs must depend on the same basic equations.

The value of the present work lies in the way in which the new data draw attention to these problems. Although predictions of the velocity of movement over the whole area of the ice shelf help our understanding of the region, the direct measurements of velocity that will be made in the near future by use of satellite position fixing methods will provide an interesting test of our main conclusions.

Work on radio echo sounding by the group at the Scott Polar Research Institute has been financed by the Natural Environment Research Council, and Antarctic flying operations have been organised by the US National Science Foundation. The work has been made possible by development of radio echo sounding methods by Dr S. Evans and others, and by support from the staff and aircrews of US Navy Air Development Squadron VXE6.

Outburst in U Cephei

A SYSTEMATIC survey of the profiles of the H α line in binary stars, shell stars, Be stars and related peculiar objects is being conducted by us (and G J Peters) with the Varo image intensifier attached to the coude spectrograph of the 120-inch telescope and the 24-inch coude auxiliary telescope of the Lick Observatory. Emission at H α is found to be a more common phenomenon among the Algol-type eclipsing binaries than was thought before. Usually, but not always, the emission is best observed during the primary minimum when the light of the hotter and brighter component is either greatly reduced or completely occulted. This is in agreement with the models representing the Algol systems as evolved binaries in which mass is still being transferred from the late-type secondary component to the hotter primary star^{1,2}. Although the general picture is fairly clear, the problem remains how the on-flowing material and its angular momentum are distributed among the primary star, the disk revolving around it and a possible envelope enclosing the whole system. The purpose of our survey is to furnish quantitative data on this process.

Observations of U Cephei show that the mass transfer and disk formation may be a very variable process. Batten³ and coworkers have tried to detect emission in this system, but found either no emission or at best a marginal phenomenon. On August 8, 1974, however, we observed very strong H α emission during a primary eclipse. Photometric observations by L. McDonald accurately determined the time of mid-eclipse (1974 August 8 4345 = JD 2442267 4345 heliocentric) and the phases.

Our equipment gives a very good dispersion (17 Å mm⁻¹) and good time resolution (exposure times were 5 to 20 min), so that the behaviour of the emission line can be studied in detail. Figure 1 shows the density tracings of nine consecutive spectrograms and Table 1 gives the peak intensities of the violet and

red emission lobes as functions of phase. Our timing of the exposures was very fortunate: the first plate coincided with the beginning of the total eclipse, the third plate with mid-eclipse, and the fifth plate with the end of the total phase. Five more spectrograms were obtained in the ensuing partial eclipse. All the plates show a very strong, deep and relatively narrow central absorption core at H α . During and near the total phase, this core, and several weaker absorption lines, were the result of the secondary (G8 III–IV) component. Emission lobes appear on both sides of the H α absorption core. Contrary to the Victoria observations made in September, however, no other emission lines were observed, although some suitable lines of Fe I, Fe II, and He I do lie in the observed spectral region around H α .

Table 1 Peak intensities of emission lobes

Plate	Phase d	Fraction of period (P)	Peak intensity (continuum = 1.00)	
			Violet lobe	Red lobe
EC 12579	−0.0302	0.9879	1.07	1.49
12580	−0.0135	0.9946	1.13	1.33
12581	0.0012	0.0005	1.20	1.22
12582	0.0200	0.0080	1.33	1.15
12583	0.0337	0.0135	1.35	1.09
12584	0.0464	0.0186	1.30	1.07
12585	0.0573	0.0230	1.28	1.06
12586	0.0686	0.0275	1.20	1.05
12587	0.0803	0.0322	1.10	1.01
12588	0.0873	0.0350	1.02	1.00

At the beginning of the total phase, the red emission lobe is very strong, while the violet lobe is marginal but real. As the eclipse advances, the red lobe weakens, while the violet lobe grows in strength. Both are equally strong at mid-eclipse, and the H α profile is symmetrical. The violet lobe reached its greatest intensity near third contact, but never quite matched the peak intensity of the red lobe on the first plate. This suggests greater accumulation of material on the impact side of the primary star. As the primary component gradually emerges from the total eclipse after phase 0.02P, both emission lobes decline in intensity, but the violet lobe remains stronger.

Qualitatively, this sequence of events agrees with the model of a rotating ring around the primary component, originally proposed by Joy⁴ for RW Tauri. For the first time, however, the dispersion and time resolution have been so good as to permit a quantitative analysis of the profiles, which is under way.

This complete ring—or better disk—must have been formed very recently. Previous observations³ indicate only a 'bridge' of material between the two components⁵, while Huang and Struve⁶ predicted that emissions in U Cephei and a few other similar systems should occur intermittently. It is probable that the primary cause was an outburst of the secondary component, with the ensuing increase in the rate of mass transfer. If so, photometric timings of future minima should show a jump in the period.

We suspect a real change in the structure of the disk within the month that elapsed between our observations and those by Batten *et al.*⁷ The seven-colour intermediate-band photometric observations made by L. McDonald simultaneously with our spectrographic observations show distortions in the light curve near the onset and the end of the total eclipse. The duration of

Fig. 1 Density tracings of the H α region on nine spectrograms taken on August 8, 1974. Tracings are superimposed so that the absorption cores nearly coincide. Laboratory wavelengths in Angstroms are indicated on the λ axis.

the total phase seemed to be much shorter than usual, but in most colours this cannot be simply interpreted as the consequence of an increased photospheric radius of the primary star. Rather, one must invoke a 'third light' in the system. Somewhat similar but weaker bumps in the light curve of RW Tauri observed by Grant⁸ were interpreted by him as the light of the emission lines. Line emission cannot be responsible for the entire effect in U Cephei.

Outbursts of this type may be fairly frequent in the Algol-type binaries, and their observations should contribute greatly to our understanding of the mass transfer processes in close binary systems.

We thank L. McDonald for preliminary information on his photometric observations, H. L. Burger for assistance, and R. C. Crawford for the Figure.

Outburst of U Cephei

We believe that our recent observations of the eclipsing binary U Cephei have implications for the study of the evolution of binary systems and the understanding of novae.

The system U Cephei contains a B7 V star of mass $4.2 M_{\odot}$ and radius $2.9 R_{\odot}$ and a G8 III-IV star of mass $2.8 M_{\odot}$ and radius $4.7 R_{\odot}$. The radius of the circular orbit is $14.7 R_{\odot}$, and the orbital inclination is close to 90° (ref. 1). The orbital period of approximately 2.5 has been increasing throughout the nearly 100 yr that the star has been recognised as an eclipsing binary. The average rate of increase is about 5 parts per 10^6 per cycle, but there are irregular abrupt period changes superimposed on the average increase, and the present rate of increase is faster. The average rate can be explained as a result of transfer of matter from the G8 star to the B7 star, and is one of many pieces of evidence for the existence of gas streams in this system.

During the total eclipse of the primary star, in systems of this sort, one can often observe emission lines superimposed on the spectrum of the secondary star. These lines originate in the gas streams, but in spite of the strong evidence for such streams in U Cephei, emission of this kind has been reported in the spectrum only once², and that was very weak. During the eclipse of September 7, 1974, however, very strong emission was observed by one of us (B. W. B.) in the course of a routine programme of observation of this and similar systems. The emission was clearly present in all Balmer lines from H β to H18 (Figs 1 and 2b), and also in the H and K lines of Ca II, $\lambda 4481$ of Mg II, and possibly in some lines of Fe II and He I. The changing intensities of the red and violet components during the course of the eclipse suggest that the emission arises in a disk that rotates around the primary star with an average velocity close to 250 km s^{-1} (Fig. 1). This emission persisted and was seen during all

the observable eclipses in September and early October. By October 17, however, it had appreciably weakened. During the same time, emission was visible at H α even in full light. For about a week in the middle of September this H α emission was accompanied by a sharp absorption component, which could also be seen at H β , H γ , and H δ , with a displacement to the violet corresponding to a velocity of several hundred km s^{-1} (Fig. 2a). This component shows large variations, on September 15, about 0.25 P after primary minimum, its displacement corresponded to -620 km s^{-1} , on September 16 at 0.67 P to -350 km s^{-1} , on September 21 (at almost the same orbital phase) to -250 km s^{-1} , and on September 22 (at the end of primary eclipse) to approximately -700 km s^{-1} . The disk around the primary star seems to have been expanding, and some matter probably left the system. During September the spectrum of the primary star changed, lines of He I almost disappeared, while those of Ca II, Mg II, and Si II became stronger. Lines of Fe II previously

Fig. 1 The change of emission intensity at H β with phase during the eclipse of September 7, 1974. The normal emission-free G-type spectrum has been subtracted from the observed spectra. Exposure times for each plate were about 45 min. The upper (first trace) was centred about 1 h before, the second (middle) about 10 min before, and the third about 40 min after the estimated time of mid-eclipse. The horizontal scale, referred to the rest position of H β is approximate.

Fig. 2 *a*, Rectified intensity tracing of the line profile of H α on September 16, 1974, referred to the continuous spectrum in full light. The zero of the velocity scale is the approximate rest position of H α . The dashed symmetrical profile is the normal absorption profile of H α displayed by an amount appropriate to the orbital phase. The displacement of the violet absorption, over 400 km s⁻¹, is greater than the amount quoted in the text which is the mean for the lines H α , H β , H γ , and H δ . *b*, Rectified intensity tracing of a region of the spectrum of U Cephei made from a plate obtained about one hour before mid-eclipse on September 7, 1974. The normal emission-free G-type spectrum has been subtracted from the observed one, but there is still some contribution from the B-type spectrum. The wavelength scale is approximate.

invisible appeared in the spectrum; especially prominent amongst them is the triplet $\lambda\lambda 4924, 5018, 5169$ which is normally barely visible but which was also seen in October 1969 when emission was last observed in the system. The spectral type is more like B9 or A0 (the original Henry Draper type) than the normal B7. Photometric measurements out of eclipse in late September showed that the $(B-V)$ colour of the primary star had changed to 0.0 mag from its customary value of nearly -0.1 mag. The $(U-B)$ colour, however, had not greatly changed.

Photometric observations during eclipse show a changed form of light curve that has also been observed by Plavec and Polidan³ and by Olson⁴ and which is illustrated in Fig. 3. We believe that the abrupt change of slope during ingress is real, but we cannot yet explain it. Note that totality is shorter than normal, but the duration of the whole eclipse seems longer than usual. During totality, the V magnitude and $(B-V)$ colour of the secondary star are normal (as is also the secondary spectrum). The $(U-B)$ colour is different; the secondary component has always shown an ultraviolet excess (compared with other G8 III-IV stars) of about 0.1 mag. During this outburst the excess has been up to 0.2 mag greater, that is $(U-B) = 0.25$ mag. We believe that this is a decisive argument against ascribing the excess to metal deficiency of the secondary star. There is some indication that the system as a whole is slightly fainter than usual out of eclipse, but the difference does not exceed 0.05 mag, and because our photometric system is not precisely the U, B, V system we are not sure that the difference is real.

The key to our interpretation is that although totality is shorter than usual, during the total phase nothing except the U magnitude is different. The secondary star, therefore, is in its normal state. If the primary star has formed a new effective photosphere, appreciably larger than the normal one, then both the decrease in the duration of totality and an increase in that of the whole eclipse would be inevitable. The new photosphere would have to have a lower temperature than the old one did, because the out-of-eclipse brightness of the system has not greatly changed. The duration of totality differs from eclipse to eclipse, and even from colour to colour at the same eclipse. On September 12, totality lasted about 50 min (0.014 P) instead of just over 2 h (0.037 P)—the normal value. Since the sine of the

phase angle of second contact is given by the difference in the radii of the two stars divided by their separation, and the radius of the secondary star is apparently unchanged, these figures imply a radius for the effective photosphere of 4.1 R_{\odot} —an increase of 42%. If the radiating surface is to increase by this amount without changing the total luminosity of the system, its temperature must be decreased by a factor 0.84. According to Morton and Adams⁵, a B7 V star has an effective temperature of 13,600 K, and this must therefore be reduced to 11,400 K—appropriate to a spectral type between B8 and B9 and not inconsistent with the changes observed in the spectrum and the $(B-V)$ colour. The proposed effective photosphere could have been created either by an exceptional ejection of matter from the G8 star, or by an expansion of the outer layers of the B7 star. We incline to the latter possibility because of the evidence for the expanding shell, and the apparent normality of the G8 star. The instability of the B7 star may, however, have been triggered by an earlier unobserved eruption of the G8 star.

Fig. 3 Photometric observations of U Cephei with a V filter on September 27, 1974 (filled circles) compared with normal points derived from similar unpublished observations by Broglia in 1957-8 (open circles). Observations from Victoria in 1971 and 1973 fit Broglia's light curve perfectly, but do not cover it completely. Times of the four contacts for Broglia's curve are indicated on the time axis. The times of mid-eclipse, determined separately for each light curve, have been made to coincide. The line indicating full light at 6.85 mag refers to Broglia's curve. Note that even the undisturbed light curve is asymmetric.

Our observations and those of ref. 3 show that U Cephei has been active throughout August, September, and part of October 1974. Spectral scans made in early July by Rhombs (private communication) suggest that some changes were taking place even then. Photometric and spectroscopic observations by us in September, 1973, showed the system to be normal and without emission then. The photometry was confirmed at the end of September, 1973, by Coyne⁶. So the outburst could not have begun earlier than October, 1973, nor later than July, 1974. Our most recent observations suggest that it is ending in October, 1974: the emission is weaker, the lines of ionised metals are disappearing from the primary spectrum, and the light curve has more nearly its usual shape. We believe we may have observed the mechanism of an abrupt period change in progress. Bakos and Tremko⁷ have reported a much smaller distortion of the light curve that they observed in August, 1969, a few weeks before emission was first detected in the spectrum of U Cephei. Hall⁸ has also reported large changes in the light curve of RW Persei. The detailed spectroscopic and photometric coverage of this incident by several independent groups is so far, however, unique in the study of close binary systems.

Further study of our observations will undoubtedly improve our understanding of the process of mass transfer in systems of this kind. We also believe it will have implications for our understanding of novae. The expanding shell and the larger and cooler

temporary photosphere are found in novae. The binary nature of many ex-novae has been demonstrated, and it is generally accepted that nova eruptions are in some way linked to the presence of a close companion. Most theories are based on the assumption that the seat of the eruption is a degenerate star (see ref. 9). The present observations suggest that something similar can take place in a system containing a main-sequence star.

We thank the observers who helped to obtain spectrograms.

High-frequency radio observations of the Stephan's Quintet region

RADIO observations have been reported for several apparently interacting astronomical systems¹⁻⁴. These observations do not provide conclusive data as to the frequency of occurrence of radio emission from multiple systems compared with that for normal galaxies. Although the detected radio fluxes do not generally fall in the 'radio galaxy' range, there is evidence that for some interacting systems at least, there is a statistical excess of the number of radio sources in their vicinity^{5,6}. The aperture synthesis observations mostly show sources coincident with member galaxies; a few show emission from regions between the galaxies. In the case of Stephan's Quintet, observations⁷ with the Westerbork Synthesis Radio Telescope (WSRT) at 1.415 GHz suggest an arc-shaped source partially encircling a point source centred on NGC7319.

The National Radio Astronomy Observatory three-element interferometer was used at frequencies of 2.695 and 8.085 GHz, between January 1 and July 3, 1973, to synthesise areas of 18' × 18' and 6' × 6' respectively, centred at $\alpha = 22^{\text{h}} 33^{\text{m}} 48.0^{\text{s}}$, $\delta = 33^{\circ} 41' 00''$ (1950) near Stephan's Quintet. Observations were obtained at 16 telescope spacings from 100 to 2,700 m. The resulting synthesised beamwidths at the two frequencies are 9" by 6" and 3" by 2" respectively, (both at position angle 324°), with the close-in side lobe levels less than 30%.

In the present observations, the point source of ref. 7 is detected at both frequencies but appears somewhat extended. This source was successfully subtracted from the synthesised map by a model at 2.695 GHz composed of a 10.4 mJy point source, with a 3.1 mJy slightly extended component 1" east

Fig. 1 The 2.695 GHz observations are superimposed on a 200-inch print of Stephan's Quintet. The cross represents source No. 1 which has been subtracted from the map. The synthesised beam is given in the lower left corner. The outer 2.695 GHz contour level is at 1.2 mJy (1 r.m.s. = 0.5 mJy) increasing thereafter in intervals of 0.8 mJy.

and 3" south of it. The same model with fluxes of 2.5 and 1.3 mJy respectively, fits the 8.085 GHz observations; the latter flux is more than four times the root mean square flux at that frequency. In the subtraction procedure used, no single point source in the vicinity sufficed to remove the observed source; the two component model was the best at minimising the residuals. This indicates that the source is definitely extended. Furthermore, the crescent-shaped source is clearly resolved at the lower frequency into two extended sources, roughly coincident with the peaks seen in the map of ref. 7. Both sources are below the detection limit at the higher frequency.

In Fig. 1, we present the results of our 2.695 GHz observations, superposed on a 200-inch photograph provided by H. C. Arp. This superposition is based on an overlay program for the Palomar Sky Survey, which, because of the small scale of the latter, can result in a displacement error as large as 15" in spite of the much higher positional accuracy of the interferometric observations. As in the WSRT map, our source No. 1 is centred on NGC7319. Source No. 2, corresponding to the northern source of the crescent of ref. 7, seems to lie on a blank field. But source No. 3, the southern source, falls quite near the HII emission features seen by Arp⁸ in the spiral arm of NGC7318b. Source No. 4 seems to be quite near a small faint compact galaxy. The slight discrepancy between our positions for sources 2 and 3 and those shown on the overlay of ref. 7, can be explained by the displacement error.

Table 1 Source data

Source	RA (1950.0) (±0.19 s)	Dec. (1950.0) (±2")	$S_{2.695}$ (mJy) (±0.5)	$S_{8.085}$ (mJy) (±0.3)	$\alpha_{1.400}^{2.695}$ (±0.3)	Remarks
1	22 h 33 min 45.9 s	+33° 42' 57.8"	13.5	3.8	1.1	Source on nucleus of NGC7319
2	22 h 33 min 42.2 s	+33° 43' 39.9"	3.2	<1.5	<1.7	Source within the crescent
3	22 h 33 min 42.2 s	+33° 42' 02.9"	5.1	<1.5	<1.7	Source within the crescent
4	22 h 33 min 35.4 s	+33° 38' 54.0"	5.5	—	1.5	Out of 8.085 GHz field of view

Our observations do not reveal the arc structure seen in the WSRT map. In order to examine the possibility that the arc may have resulted from a blending of our two sources in the lower resolution map, we have convolved our observed map with a larger beam approximating the WSRT resolution. The resulting map still showed the two sources well resolved. We conclude that the apparent discrepancy results from either of two possibilities. Firstly, that such an arc does indeed have a continuous distribution as seen in the WSRT map, but that the continuity is broken at our higher frequency by the weakness of the emission at all areas other than the peaks. If the whole arc structure has as steep a spectrum as the two sources, (as seen in Fig. 2), then the flux density level received from the rest of the arc would never exceed three times our r.m.s. level. Secondly, the structure may be a blend of four or more sources, of which only two are within our detection limit at 2.695 GHz.

Fig. 2 Spectra of sources in Stephan's Quintet area. \times , present observations; \circ , WSRT observations².

No distinction between these two alternatives can be made with our present observations.

Table 1 shows the positions, fluxes, and spectral indices, α , for sources detected within the larger area observed. The r.m.s. errors are listed at the top of the respective columns. All fluxes have been corrected for gain of the primary beam.

In Fig. 2 we show the spectra of the three resolved sources seen within the quintet and the fourth source detected about 5' south preceding NGC7319. The 4.995 GHz flux value for source 1 is from preliminary observations by Allen (unpublished). In the case of source 4, the 1.415 GHz peak flux was read from a full field map provided by Allen (unpublished).

The most striking feature of the spectra is their steepness. Indeed, with the exception of source 1 (which falls on NGC7319), all three indices exceed the 1.3 limit observed for most extragalactic sources⁹. It is tempting to speculate that the extreme steepness of these spectra together with the extended forms of the sources may indicate that they are remnants of an earlier ejection, at least for the sources in the arc, and that the source centred on NGC7319 is of a later epoch. It should be pointed out, however, that the extreme steepness of sources 2 and 3

would be somewhat reduced if some flux were present due to an extended component that we failed to detect.

An interesting and less speculative conclusion results from the comparison of single dish observations of the area with the present high resolution measurements. Two of us⁶ have noted the probable existence of a ridge of radiation in the area of Stephan's Quintet at low frequencies. Since the present interferometric observations are insensitive to extended sources, certainly beyond about 3 arc min in extent, any excess found in a single dish measurement over the sum of the small sources falling within its beam would confirm the existence of such a ridge. Such single dish measurements within the spectral range shown in Fig. 2 (eliminating the need for extrapolation) have been made by Arp¹⁰, at a frequency of 2.295 GHz. Interpolation of the fluxes for the four sources, all falling within the beam of Arp's measurements gives a value of 34 ± 2 mJy. A similar interpolation using the whole extended arc of WSRT gives a value of 40 mJy. Arp's single dish measurement gives a value of 90 ± 10 mJy, well over twice the value expected from either of the above interpolations. We thus conclude that the evidence for a structure of ≥ 3 arc min in extent suspected at low frequencies is strengthened by the present results which strongly support the existence of a broad component at the higher frequencies.

We thank Dr R. J. Allen and Professor H. Arp for their comments and the former for providing us with preliminary data before publication. One of us (M.A.K.-K.) was partially supported by an NSF Travel Grant. NRAO is operated by Associated Universities, Inc., under contract with NSF.

Seismographic observation at the bottom of the Central Basin Fault of the Philippine Sea

THE Central Basin Fault of the Philippine Sea is proposed as an extinct mid-oceanic ridge^{1,2} and seems to be a key to the development of the floor of the Philippine Sea. Though the fault seems to be aseismic on the basis of land networks, it is interesting to know whether microearthquakes occur in the vicinity of the fault. We put a sensitive ocean-bottom seismo-

Fig. 1 Locations of observation sites of ocean-bottom seismographs. Bathymetric map (depths in fathoms) is reproduced from HO 1301 publication. Intersection lower left is a record of ship-borne depth recorder of RV Hakuho-maru. Position of A: $15^{\circ}06'N$ ($15.10^{\circ}N$), $129^{\circ}54'E$ (129.91°). Position of A': $16^{\circ}43'N$ ($16.71^{\circ}N$), $131^{\circ}15'E$ (131.24°). Direction from A to A': 39° (perpendicular to the fault); distance from A to A': 233 km.

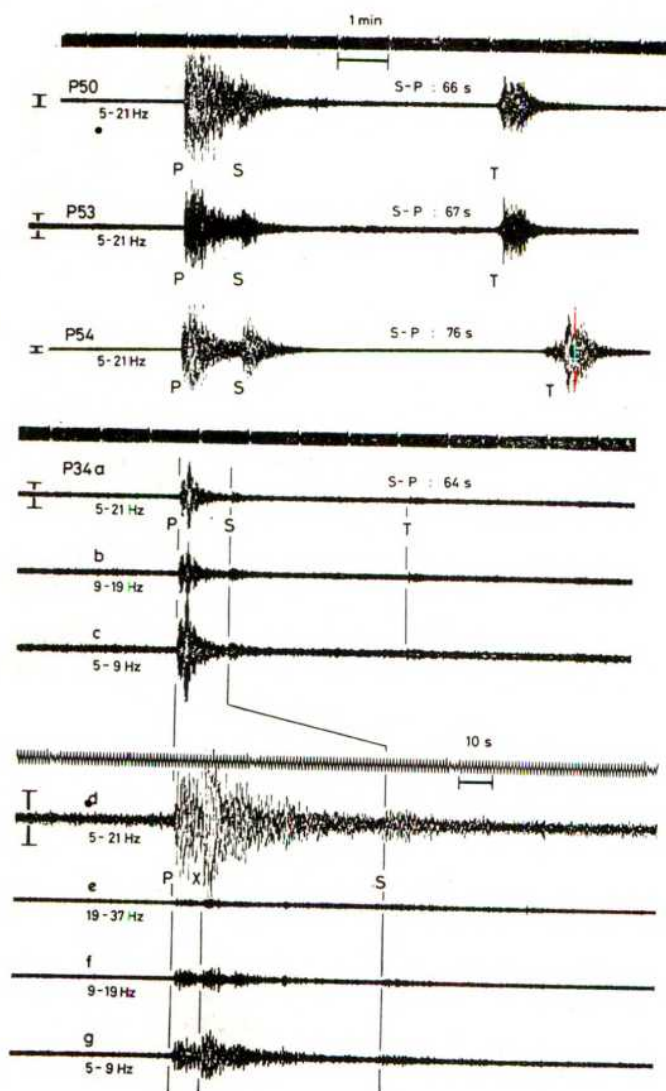

Fig. 2 Some earthquakes recorded by OBS. Number of events, frequency band of band-pass filters which were used in reproduction of magnetic tapes, S-P time as indicated. T phase travel time data support the view that the velocity of T is 1.5 km s^{-1} . Equivalent ground velocity amplitudes of $15 \times 10^{-6} \text{ cm s}^{-1}$ are also shown by bars on each trace. The X-phase is discussed at the end of the paper.

graph (OBS) in the median valley of the ridge (the width of which is only a few kilometres) and from its recordings have been able to deduce the existence of microearthquakes. It has also been possible to estimate P and S velocities for the top of the mantle and a Q structure for the upper mantle.

Seismographs have been developed over the past few years^{3,4} for seismographic survey in the vicinity of deep sea trenches of the western Pacific⁵ and for long-range explosion experiments in ocean basins⁶. The instruments were intended to record low level seismic signals and were designed to be buried in the ocean sediment to avoid the noise generated by ocean-bottom water currents.

The position of the bottom seismography (by satellite navigation) was 16.03°N , 130.72°E (Fig. 1). The depth was 6,500 m and the bottom was covered by sediment. The recording period was about 63 h, from 0930 GMT on September 16 to 0030 GMT on September 19, 1973. More than 120 earthquakes were recorded, none in the vicinity of the observation site. Considering the sensitivity of the seismograph, no earthquake whose magnitude was more than -3, 0 or 1 occurred within 20, 100 or 250 km of the observation site. All the earthquakes observed, except one, took place beyond the edges of the Philippine Sea

plate as they have S-P times of more than 64 s. The exception was an earthquake with an S-P time of 25 s, and a magnitude of about 2.

The numbers of earthquakes recorded, 2 h^{-1} , and the distribution of S-P times indicate high sensitivity of the bottom seismograph (the distances from epicentres being more than 700 km) and a high level of seismicity along the Philippine and Ryukyu trenches.

Travel times of an earthquake near Taiwan, located by the WWSSN network (0709 GMT on September 18, 24.9°N , 122.0°E , $h = 86 \text{ km}$, $M = 4.9$), show that the mean V_p value is 7.9 km s^{-1} and mean V_s value is 4.6 km s^{-1} , when the epicentral distance is 1,340 km. The mean V_p value is considerably lower than the 8.2 or 8.3 obtained in the western Pacific Basin for similar epicentral distances (T.A., H.S., Y.T., and K. Kobayashi, unpublished). The S-P velocity is 11 km s^{-1} . The value of V_p indicates that the upper mantle velocity beneath the Philippine Sea is considerably smaller than that of normal ocean basins.

The seismograms we recorded have strangely small amplitudes of S phrases (Fig. 2). Although only a vertical seismometer (natural frequency 3 Hz) was used in this observation, the marked diminution of amplitudes of S waves contrasts markedly with seismograms of similar S-P times recorded at the other observation sites of our bottom seismographs. It is probable that shear waves are greatly absorbed in the upper mantle beneath the Philippine Sea; this perhaps results from partial melting not unconnected with high heat flow data (Y. Kono, and Y. Tomoda, personal communication).

Spectral analyses of the initial part of P waves were performed. If we assume the source spectra of earthquakes, the mean attenuation factor \bar{Q} along the wave path can be calculated from the slopes of spectral curves (Fig. 3). Differences in the assumed source spectra probably result in a trifling difference in the estimation of \bar{Q} because magnitudes of earthquakes do not differ by much in this study. The estimated \bar{Q} values are shown

Fig. 3 Some examples of frequency spectra of first part (initial 3 s) of P waves. Number of event and S-P times (in parentheses) are shown at each curve. Note that high frequency components of earthquakes with S-P times of 70-80 s are more abundant than those of 64-67 s. One of Aki's source models⁸ is also shown.

Fig. 4 Distribution of \bar{Q} values. In the computation, the ω^{-1} model for the source of these frequencies (or model B of Aki⁵) was used. Although other source models will produce different absolute values of \bar{Q} , an abrupt increase of \bar{Q} value at the same range and the same depth is observed.

in Fig. 4, illustrating an abrupt increase in \bar{Q} value at a distance of about 800 km. This suggests that a high \bar{Q} layer exists. The depth to the boundary of this steep increase of \bar{Q} value cannot be accurately estimated because the velocity structure is not known, nevertheless it is about 80 km if we assume the Japanese Meteorological Agency travel timetable, which fits well in and around Japan. Although \bar{Q} values of about 2,000 are higher than those of island arcs such as Honshu, the values are still considerably lower than those of ocean basins obtained from other OBS observations.

Most of the recorded seismograms have clear secondary arrivals at 8–9 s after onsets of P waves (see the X-phase on Fig. 2).

This peculiar phenomenon can be explained if the secondary waves are P to S conversions at the boundary at which \bar{Q} value is abruptly increasing. The highly attenuative zone underneath the western part of the Philippine Sea is probably bottomed by a high \bar{Q} layer at a depth of about 80 km. This structure is quite different from that of the north-west Pacific Basin (T A, H S, Y T, K Kobayashi, S Murauchi, N Den, and T Asanuma, unpublished) and could be peculiar to extinct mid-oceanic ridges.

We thank the officers and crews of RV Hakuho-maru of the University of Tokyo for help in laying and recovering the OBS.

Bounds on the P velocity for the whole Moon

THE hedgehog algorithm suggests that either some Apollo seismic travel time data are in error (some layers dip) or a high velocity lid exists at a depth of 60 km in the Moon. The velocity depth curves for the Moon derived from the Apollo seismic data^{1,2} are probably not representative of the Moon as a whole and lateral inhomogeneity in the near surface layers can affect the generality of measurements of arrival time and amplitude.

We are particularly cautious about amplitude data, as plausible lateral variation in the near surface layers of the Moon can result in substantial errors in the estimates of ray

Fig. 1 Initial models for a hedgehog search of lunar structures ———, Class A, — — —, class B, — · — · —, class C

parameter based on a radially homogenous Moon. Since amplitudes depend on derivatives of ray parameters we suggest that the use of amplitude data to elucidate lunar structure is premature.

The first few kilometres of the Taurus-Litrow region of the Moon have a step-wise velocity depth structure compatible with a series of lava flows³. Travel time differences of up to 1 s can arise if the thickness of any lava layer

Table 1 P wave travel times used in the inversion

Delta (degrees)	Travel time (s)	Weights
0.287	5.57	4.0

3.07	22.0	1.75
3.76	25.0	2.0
4.45	28.6	2.0
5.18	32.0	2.0
5.67	35.7	2.0
6.07	26.6	2.0
11.2	57.0	2.0
11.8	55.0	2.0
—	61.0	2.0
28.0	123.1	2.0
34.0	155.1*	2.0
	151.0*	1.5

*Only one of these two arrivals was used, in class B models, which one is used affects the half space velocity acceptance region by about 0.5 km s⁻¹.

is doubled or halved. As such variations would introduce errors in any analysis which considers the Moon to be laterally homogeneous, we add them to those observational errors which we have estimated as 0.5 s from a few sample seismograms¹. We considered variable accuracy by assigning weights based on discussions in the literature^{1,2}.

Solution of the inverse problem for such a set of travel time observations is well suited to the hedgehog algorithm⁴. This algorithm can deal with amplitude data and with travel times. Until the effect of intensive scattering is understood and synthetic seismograms can be made to fit substantial portions of lunar seismograms, however, we hesitate to use such data.

We used three models (Fig. 1) as a starting point in our search for a range of models which would fit the data within the accuracy of the experiment. The criteria for fit are: (1) the root mean square error of fit shall be less than σ , (2) no more than j time observations shall differ from computed times by k times the weight W_i of the i th phase.

Table 2 P wave travel times*

Delta (degrees)	Travel time (s)	Weights
11	10.5	2.0
15	14.0	2.0
19	17.5	2.0
518	35.5	2.0
112	54.0	2.0

*Note the considerable uncertainty in these points. They were read from a graph of travel times prepared by Toksoz *et al.*¹

We used various values for σ , j and k , and coarse searches in which positions were changed by increments of 10 km and velocities by increments of 1 km s⁻¹, together with fine searches with increments of half this size. We could not find any acceptable models of class A (Fig. 1) with any reasonable set of σ , j , k values. The data for the triplication (from either Table 1 or 2) suggest a half space velocity of 9.5 km s⁻¹ while the travel times near 30° suggest a velocity of 7.75 km s⁻¹.

Class B models all have a poorly resolvable low velocity zone (LVZ) at a depth of about 100 km. With an LVZ

Fig. 2 Various solutions for the lunar velocity depth curve. The lines are published^{1,2} solutions using both amplitude and travel time data. The cross-hatched area is the region delineated by a fine hedgehog search. The lined area plus the cross-hatched area is derived from the coarse search. The stippled area illustrates the uncertainty caused by discrete steps taken in the hedgehog search.

	1,032	151.0	2.0
		155.1	2.0

*30.3 km = 1° on the lunar surface

These observations depend in part on an assumed model of the Moon's mantle

located at this depth we have no direct P arrivals near 30°. Multiples (for example, PP) may be possible. If the arrivals at about 1,000 km are PP: (1) Using data in Table 1, together with the acceptance criteria ($\sigma=2.8$, $j=0$, $k=1.2$) and a coarse grained search, we found some acceptable structures (Fig. 2). (2) Using data in Tables 1 and 2 ($\sigma=6.0$, $j=0$, $k=2.4$) and a fine search we found additional acceptable structures. (3) Using data in Tables 1, 2 and 3, no acceptable solutions were found in a search based on ray theory alone. If the uncertainties (σ and k) are reduced to half the values in cases (1) and (2) there are no acceptable solutions on the basis of a fine search. If the data in Table 3 are in error by more than 10 s, solutions (1) or (2) are correct, otherwise, models A and B are inadequate. If class B models and Fig. 2 are accurate, high velocities in the first half space raise strict petrological constraints¹. Class C models are characterised by a thin lid of high velocity. Classical ray theory is not applicable in a thin layer. We expect, instead, a head wave in the lid whose low frequency components will tunnel into the low velocity zone beneath it. This tunnelled phase will be effectively low-pass filtered while the headwave is high-pass filtered.

The anomalous data at 1,000 km can be interpreted as a combination of tunnelled waves and head waves⁵. The velocity at the top of the lid is between 8.0 and 9.5 km s⁻¹, below which a constant velocity (7.25–7.75 km s⁻¹) half space exists. A thin high density garnet layer would be stable at this depth in the lunar interior⁶.

With the exception of the first 8 km of the Moon and the mantle velocity, the range of our solution spans published solutions which have used both travel times and amplitudes. We used a one parameter model for the near surface structure. Had we used a more complex model our solution would also have spanned the published solutions in the near surface layers. We feel that detail in the near surface layer is an unjustified complication. The discrepancy below 1,665 km is resolved if head waves and tunnelled waves exist in a high velocity lid.

We thank G. V. Latham for making available the data in Table 1, and M. N. Toksoz for the results in Table 2.

Short period teleseismic S waves

SHORT range observations of short period S waves are useful in determining the distribution of zones of high and low anelastic attenuation in the vicinity of island arcs¹⁻³. We show here that S waves are also recorded at some stations at teleseismic ranges and that these recordings can be used to study anelastic attenuation.

S waves are useful because they are more sensitive to changes in anelasticity than P waves. The attenuation of body waves at angular frequency ω is given by $\exp(-\omega t^*/2)$ where $t^* = T/Q_{av}$, T is the travel time and Q_{av} the average quality factor Q , for the raypath and the particular wave type. As S wave travel times are about $\sqrt{3}$ of the travel times of P waves, and Q_p is about $4/9$ Q_s (making the usual assumptions that anelasticity affects only the shear modulus of rocks^{4,5} and that Poisson's ratio is around 0.25), t^* for P waves (t_p^*) is roughly a quarter of t^* for S waves (t_s^*). Thus, for an S wave travel

Fig. 1 Observed (a-c) and modelled (d-f) S wave seismograms showing double arrivals. The later arrivals on the observed seismograms are interpreted as true S waves and the preceding arrivals as S to P conversions at the Moho beneath the receiver. The modelled seismograms include no effects of layering in the source region, all the arrivals are generated from a single S wave arrival at the base of the receiver crust. Note that the PcS wave for earthquakes at the depth and distance illustrated in c (P wave reflected from the core as an S wave) arrives just before the S-P arrival. a November 2, 1972, Loyalty Islands, origin time 19 h 55 min 22.1 s, $m_b = 6.3$, $\Delta = 32.40^\circ$, $h = 32$ km. b October 26, 1972, New Hebrides Islands, origin time 22 h 48 min 34.4 s, $m_b = 5.4$, $\Delta = 31.9^\circ$, $h = 157$ km. c March 9, 1971, south of the Fiji Islands, origin time 08 h 11 min 52.8 s, $m_b = 5.0$, $\Delta = 42.4^\circ$, $h = 511$ km. d, $t_p^* = 3.5$, e, $t_p^* = 1.3$, f, $t_p^* = 0.7$.

Table 1 Crustal model for receiver crust

	P wave velocity (km s ⁻¹)	S wave velocity (km s ⁻¹)	Density (g cm ⁻³)	Thickness (km)
1st layer	5.6	3.2	2.8	12.0
2nd layer	5.9	3.4	2.8	12.0
3rd layer	6.2	3.6	3.2	14.0
4th layer	8.3	4.8	3.4	∞

time of 1,000 s an increase in anelasticity that produces an increase in Q^{-1}_p of 0.001 gives, at 1 Hz, 10 times more attenuation of S waves than of P waves. Short period S waves are difficult to detect at teleseismic distances because for many paths through the Earth t_p^* is apparently about 1.0 s or greater^{6,7} so that t_s^* will be 4.0 s or more. Thus (at 1 Hz), S waves will be about 10,000 times smaller than P waves, at the receiver, other things being equal.

Values of t_p^* in the range 0.2-0.5 s have, however, been reported^{8,9} on some paths, suggesting that differences between the attenuation of P and S waves for these paths should be in the range 10-100. Short period S waves should, therefore, be detectable at long ranges. A search of recordings from array stations Yellowknife, Canada (YKA) and Warramunga, Australia (WRA) shows that both stations do sometimes record short period S waves from earthquakes with (US Coast and Geodetic Survey) body wave magnitudes greater than 4.8. The largest S waves relative to P waves are from deep earthquakes. As most attenuation is thought to occur in the asthenosphere at depths in the Earth of 100-300 km, and the

Fig. 2 Dominant period of direct P and S waves observed at WRA as a function of the depth of the source, combined data from Tonga-Fiji (\square, \times) and New Hebrides (\bullet, \circ) regions.

asthenosphere is thought to thin under shields, then observations of large S waves from deep earthquakes at stations such as YKA and WRA, which are situated on shields are just what is expected (compare Fig. 1a and c).

The largest number of S waves that we have obtained are from WRA for the Tonga-Fiji and New Hebrides regions, and as these are the regions where Q has been most extensively studied at short ranges, we shall concentrate on these observations.

Figure 1 (a, b and c) shows WRA recordings of SV waves (the array contains only vertical component seismometers) from three earthquakes. All the examples show two distinct arrivals separated by 6 s, both have apparent surface velocities close to those predicted by S wave travel-time tables. The second of the two pulses seems to be a true S wave, the first is interpreted as a P arrival generated by S to P conversions at the base of the crust at WRA. Explanations such as double sources can be ruled out because the P waves show no similar double arrivals, and the possibility that the second pulse is a depth phase can be discarded because the double pulse is generated by earthquakes at all depths with a constant separation of about 6 s.

The existence of P precursors to SV have been suspected for many years Jeffreys¹⁰, for example, proposed them as an explanation of the difficulties that occurred in reconciling P and S travel times, for it seemed that S waves from many earthquakes arrived earlier than predicted

The double pulse can be modelled theoretically (Fig 1d, e and f) using the method described by Hudson^{11,12}; the WRA crustal structure used (Table 1) is based on a model¹³ for the Canadian Shield Kanesewich¹⁴ *et al*, have made similar theoretical calculations and discussed the implications of precursors to S waves, and Báth and Stefánsson¹⁵ have observed precursors to S waves at teleseismic distances on long period instruments. The examples shown here seem however, to be the first short period observations of such precursors at these distances, although Smith¹⁶ has observed similar effects from local earthquakes

To ascertain the effects of attenuation we measured the dominant period of the P and S waves as a function of the depth of focus (see Fig 2 and ref 2). As there are no obvious differences between the data from Tonga-Fiji and those from the New Hebrides they are both shown on the same figure. The results show an increase in the period of both the P and the S waves with decreasing depth of focus for depths shallower than 250 km but, as expected, the increase in period is much more pronounced for S waves than for P waves. Assuming that these differences in period can all be attributed to the effects of anelastic attenuation it is possible to deduce a rough *Q* structure for the upper mantle in the Tonga-Fiji and New Hebrides regions (Table 2). The structure was obtained by modelling P and S recordings for a range of values of t^* and measuring the predominant period of the resulting seismograms. Using this relationship between t^* and period, we estimated the value of t^* for paths to WRA for each depth of focus (using the smoothed curves drawn through the data, Fig 2). The upper mantle was then divided up into a series of layers in which *Q* is assumed constant, and the *Q* structure was derived using the time spent in each layer by rays travelling to WRA for each depth of focus.

The result shows very low *Q* values at depths shallower than about 200 km in both the New Hebrides and Tonga-Fiji regions. The low *Q* in the Tonga-Fiji region seems to coincide with the zone of "extremely low *Q*"² beneath the Lau Basin west of the Tongan Ridge, although we shall have to use ray tracing to work out the details of structure. The similar zone of extremely low *Q* lying to the south and west of the New Hebrides region does not seem to have been reported previously.

Table 2 Approximate *Q* structure for the upper mantle

Depth (km)	Q^{-1}_a	Q_a	Q^{-1}_b	Q_b
0-100	0.0250	40	0.0500	20
100-225	0.0110	90	0.0220	45
225-600	0.0010	1,000	0.0033	300
600	0.0004	2,500	0.0008	1,250

In deriving the *Q* structure we have made the assumption that any source effects on the observed period can be neglected. This is probably an oversimplification, it may be that for shallow sources the pulses radiated are of longer duration and, therefore, the ratio between high frequency energy and low frequency energy is lower than for deeper sources. We have, however, found it impossible to model seismograms showing S waves with a period of over 2 s by increasing the source size while obtaining a good fit to the P phase at the same time. For example, PKiKP is visible for the Loyalty Islands earthquake (although not illustrated in Fig 1a) as a single wavelet with a period of 0.8 s, and the S phase for this earthquake has

a period of 2.5 s. With the source model used here these differences in period cannot be shown as an effect of source rather than of attenuation.

Possible mechanism of continental breakup in the North Atlantic

New observations from the Skaergård area have provided evidence relating to the mechanism of continental breakup in the North Atlantic. The East Greenland coastal flexure and its associated dyke swarm¹ has become a classic of this type of structure and has been frequently compared with similar structures around the world, notably the Lebombo monocline of south-east Africa^{2,3}. No new data have appeared in print, however, since the original description by Wager and Deer¹. I have had the opportunity to examine the structures in the Skaergård area (68°N, 32°W), and report here my observations on the mechanism of flexuring and dyke intrusion, which is believed to be very similar to structures described from areas of present spreading, such as Afar⁴.

In the original description Wager and Deer emphasised that the coast parallel dykes were intruded radially to the flexuring from a centre below surface, caused by tension resulting from the bending of a thick succession of lavas (Fig 1a). Closer examination of a 500-m profile at nearly right angles to the coast at Haengefjeldet, south of Skaergård (Fig 2), has shown that the continuous decrease in dip on approaching the coast, described by Wager and Deer is a severe over-simplification. Most of the dykes in the swarm have average dips of 90-70° N and strike 90-100°, an orientation which seems to be rather constant from the coast and several kilometres inland. All dykes have very irregular dips and several are found which have dips varying from northerly to southerly directions. Examination of the dyke chulls in the walls showed that dilatation is the normal intrusive mechanism and that the host rock in

Fig. 1 Sketches of the profile A-B (Fig. 2) showing (upper) the model proposed by Wager and Deer¹ compared with (lower) that proposed in this paper. The older generation of dykes is shown in heavy black, the younger as the thinner, approximately vertical dykes. Numbered faults correspond to those shown in Fig. 2.

several places is an older dyke swarm of thick, black, coarse-grained dykes.

This older dyke swarm which is also parallel to the coast, is very uniform in the field and in hand specimen and has low dips of $50-40^\circ$ N. It cuts the lavas, agglomerates and tuffs of the lower basalt series³, which are orientated $100/45-60^\circ$ S and so is perpendicular to these. Both lavas and older dykes are cut by numerous small shear zones and faults, now filled with carbonate and zeolites. The vesicles of the lavas are also completely filled. The mineralogy of the older dykes and the lavas has suffered from this altera-

tion such that olivine always is replaced by chlorite, serpentine, carbonate, and so on, while plagioclase is less altered and pyroxene is always fresh. The large amount of pseudomorphed olivine both in the groundmass and as phenocrysts, suggests that the older dykes were very basic olivine basalts. Chemical work on this subject is in progress and will be presented elsewhere.

In contrast, the younger main swarm with grey, green, brown and red weathering colours shows no signs of shearing and faulting and is much less altered. As suggested by the weathering colours the younger swarm is characterised by a wide spectrum of different rock types, including both aphyric and plagioclase-aphyric dolerites together with a range of intermediate to acid types. The distribution of dykes with a concentration near the coast described by Wager and Deer¹ and confirmed by my own observations, was regarded by them as being the consequence of the maximum bending of the coastal flexure in this area (Fig. 1a). It now seems, however, that the high intensity of dykes near the coast is caused by the presence of both dyke generations within 1 km from the coast, whereas only the younger generation persists further inland, at least up to 5 km, with little or no decrease in intensity.

These observations clearly show that the younger dykes were not intruded perpendicular to the lavas and that they were intruded after the tilting of the lavas. The older dykes, which, in common with the lavas, are sheared and altered, must have been formed before the flexuring, and thus neither of the generations can have formed as the result of the process described by Wager and Deer.

The faulting and shearing described in the profile at Haengefjeldet has been found in the whole of the Skaergård area, and the profile A-B (Fig. 2) will now be described in some detail. In the description of the Skaergård area, Wager and Deer⁶ noted the Sorte Kap fault 60 km inland as a normal fault with downthrow to the south and a dip-slip of at least 800 m. North of this fault the lavas dip slightly north and to the south dips are small but southerly (Fig. 1b). At the lake in Sødalen, Mikis Fjord, a normal fault was located running E-W and dipping north with a downthrow to the north and a dip-slip of several hundred metres, shown by the fact that the underlying sediments are relatively up-thrown and exposed to the south. North of this fault the lavas dip 10° S while to the south of it the dips have increased to $20-22^\circ$ S.

Although minor faults occur, dips of the lavas are more or less constant as far as 5 km from the coast along the Denmark Strait. Because of the intensity of the younger generation of dykes in the dyke-swarm along the coast, not disturbed by faults, outcrops of the lava succession are difficult to correlate, but within the last 5 km to the coast, dips change from 22° S to $45-60^\circ$ S. It is believed that this change occurs principally at two or more major shear zones, which have been seen in the outer Mikis Fjord and at Haengefjeldet.

Shear zones have been found to be very common in the coastal region but at most localities displacements are very difficult to evaluate, because of the lack of marker horizons. For example six shear zones or faults cut the Skaergård peninsula, but in only one of these could the displacement be confirmed by a dyke intersection.

These relationships in Mikis Fjord area are very similar to those described by Mohr⁴ from the western escarpment of the Afar triangle in Ethiopia. The model proposed for the East Greenland coastal flexure, is that of a similar large scale fault pattern with marginal normal faults dipping S (such as the Sorte Kap fault) and a large number of smaller northerly dipping faults near the coast with downthrow to the north, causing a rotation of fault blocks and the dip variations in the lavas.

This interpretation corresponds to a 'half' graben structure, which is consistent with the plate-tectonic origin of

Fig. 2 Simplified map of the Skaergård area, East Greenland. The Skaergård intrusion (shaded) and faults with dip directions are shown. Faults without dip signs are shear zones where the faultplane is more or less vertical and relative displacement has not been determined. 1, Sorte Kap fault; 2, Sødalen fault; 3, Mikis Fjord major shear zones (Fig. 1b).

the lower Tertiary geology of this area. Thus, Brooks⁷ described the Kangerdlugssuaq areas as the site of the Icelandic mantle plume in Eocene times, which resulted in major updoming, rifting about a triple point and subsequent crustal separation along fractures parallel to the present coastline.

As it is assumed that both dyke-swarms and the flexuring of the coast are formed in the breaking up of the North Atlantic, the correlation between dyke intrusion and major tectonic events might be explained in the following manner. As stated earlier, both the older dykes and the lavas are flexured and therefore must be older than the collapse of the coast marked by the faulting and shearing. Thus these dykes may well be correlated with the prespreading updoming described by Wager and Deer⁸ and Brooks⁷.

The younger dykes, which are not sheared and faulted, were probably formed after the initial fracturing event and could be correlated with the active spreading and new crust formation, which opened up the North Atlantic.

Finally, the recognition of intense faulting in the area indicates that extreme caution must be exercised when employing the structural heights in the Skaergård intrusion as estimated by Wager and Brown⁸. Tectonic disturbances of the intrusion would explain some of the irregularities of the Skaergård contact, which can be seen on aerial photographs and the map of Wager and Brown⁸. Such faulting would also be expected to have a profound effect on the magnitude of the hidden layered series in the intrusion, whose size has recently been questioned by geophysical⁹ and geochemical¹⁰ investigations and on estimation of the thickness of the basalt succession in the area.

I thank Professor A. R. McBirney for placing aerial photographs of the area at my disposal. Dr C. K. Brooks, Mr T. Haaland and Mr T. S. Petersen helped in the field and in the writing of this report.

Interaction between coherent light waves and free electrons with a reflection grating

A NEW effect is proposed for obtaining effective interaction between coherent light waves and free electrons. Potential applications of the effect are optical electron accelerators (linac)^{1,2} and optical amplifiers³.

Smith and Purcell demonstrated⁴ that light is emitted when a high voltage electron beam moves parallel and close to a metallic optical diffraction grating in a direction perpendicular to the grating rulings (Fig. 1a). The radiation has been explained physically in terms of the oscillations that must be executed by the charge induced on the grating surface by an electron in the beam. The dispersion relationship is

$$\cos \theta_n = (c/v) - (n\lambda/d) \quad (1)$$

with $n = 1, 2, \dots$, θ_n the angle that the direction of propagation

Fig. 1 a, Schematics of the Smith-Purcell radiation; b, 'inverse Smith-Purcell effect'.

makes with that of the electron beam, d the grating constant, v the velocity of the beam, and λ the free space wavelength of the light.

Here we consider the 'inverse Smith-Purcell effect' to obtain extended interaction of an electron beam moving along the grating surface with light incident on the surface. A simple Huygens analysis shows that when the directions of the incident light wave and the electron beam are opposite to those in the case of Fig. 1a and satisfy the condition of equation (1), the beam interacts synchronously with the wave; that is, an electron sees the same phase of the wave with the pitch of d (Fig. 1b). When the electron beam is opposite in direction to the wave on the grating surface, the synchronous condition becomes

$$\cos \theta_m = (m\lambda/d) - (c/v) \quad (2)$$

where $m = 1, 2, \dots$

When the synchronous condition is satisfied, an effective interaction must occur between the electron beam and the light wave in the same manner as the spatial harmonic interaction occurring in microwave travelling-wave tubes, leading to

Fig. 2 The Smith-Purcell and 'inverse Smith-Purcell' arrangements with a Fabry-Perot resonator.

electron acceleration or deceleration according to the relative velocities of the electron and the phase of the light wave in the interaction region. If the electron suffers net acceleration over a period of time, then electromagnetic field energy is converted into electron kinetic energy, resulting in an electron accelerator. Optical (laser) accelerators will have the unique property of providing high acceleration gradients because of the intense fields that can be obtained. An acceleration of the order of 1 GeV m^{-1} may be anticipated³. In addition, the electrons will be bunched to a dimension which is short compared to the light wavelength, giving current pulses with a time duration of the order of $\sim 10^{-15} \text{ s}$. These pulses could be used to study ultra-fast relaxation processes^{1,3}.

On the other hand, when the electrons are faster than the phase velocity of the light wave and suffer a net deceleration, light amplification may be obtained.

If the incident angle θ_k of the light satisfies the following condition,

$$\cos \theta_k = k\lambda/2d \quad (3)$$

where $k = 1, 2, \dots$, the diffracted ray direction is the same as the incident one. In this case we can adopt the configuration shown in Fig. 2. A Fabry-Perot resonator is formed with the grating and a mirror⁵. Using this configuration as a laser cavity, high intensity electric field in the laser cavity can be used to accelerate the electrons. This configuration involves the one proposed by Takeda and Matsui² as the special case of $\theta_k = \pi/2$.

The same configuration can be used to obtain 'stimulated Smith-Purcell radiation', that is, the Smith-Purcell radiation with internal feedback by the Fabry-Perot resonator. We have observed⁶ the millimetre and submillimetre wave oscillation in an electron tube called the Ledatron when $\theta_k = \pi/2$.

With recent progress in the development of high power lasers in the optical and infrared regions, it should be possible to miniaturise linacs by using the 'inverse Smith-Purcell effect' proposed here.

We thank Professor R. H. Pantell of Stanford University for communicating unpublished information.

Marked boundary layers exhibit a clearly defined reproducible pattern of streamwise streaks in their sublayers¹⁻³ and regions with higher colour concentrations are identical to those areas where liquid flow is retarded.

Observations by Fales⁴ allowed this flow structure to be explained by means of a longitudinal eddy model. As the question of this eddy structure, or its alteration in the existing models is of decisive importance^{2,5,6} in explaining the Toms effect we endeavoured to explain this problem by observation.

Fig. 2 Sand pattern experiments. a, With tap water; b, with 50 p.p.m. polyacrylamide solution.

We investigated the structures using fine sand to make the flow visible, though in fact it is not the flow itself which is observed, but the trace it leaves on the bed. As a second step we investigated the sublayer by means of the hydrogen bubbles visualisation technique.

Fine quartz sand settles evenly on the bottom of the experimental tank, and when the liquid is set in motion, the individual grains can be photographed easily, particularly when a smooth surface is used, as in this case. When we investigated integral structures, we used continuous illumination; short term movements were followed under stroboscopic lighting.

As a test device (Fig. 1a) we chose a shallow, rectangular sheetmetal trough with a smooth, black plastic foil attached to the bottom. The trough could be tipped steeply about a pivot by means of exchangeable washers, so that we could regulate the velocity of flow as a result of the tipping motion. The flow itself was also brought to a turbulent state with a trip-wire and made visible by means of fine sand. We recorded the movement of the quartz grains with a camera mounted perpendicular to the water surface. The second test was carried out in a small closed-circuit channel (Fig. 1b). The camera, or film unit, stood perpendicular to the two-dimensional flow, which was illuminated from below by a stroboscope through a glass plate.

Alteration of structures of sublayer flow in dilute polymer solutions

THE Toms effect may be assumed to be based on a phenomenon which occurs in the immediate wall layer. Models proposed to explain the effect are, therefore, mostly aimed either at producing an interaction of the molecules with the flow structure (that is, the eddies), or at attributing new rheological properties to the liquid on the basis of the molecules released, which should lead to new forms of flow.

The anode was a stretched wire 8 cm long, placed transverse to the flow and as close to the wall as possible in order to produce the bubbles in the sublayer. The cathode was used as a spillway in order to set the water depth to approximately 2 cm. The mean velocity of flow was 10 cm s^{-1} , corresponding to a Reynolds number of 2,000. As the sand tests were performed at the same Reynolds number, it was possible to compare the two results. The greatest problem, however, was the 100 p.p.m. MEYP-01 polyacrylamide solution used, because the hydrogen bubbles contributed considerably towards the destruction of the molecules and the test liquid had to be replaced with freshly prepared solution relatively quickly. For quantitative tests, therefore, the closed circuit was dispensed with, as in this case it is only permissible to work with fresh solution, which would entail substantial experimental difficulties, particularly when high demands were made of the solution's homogeneity.

But it is not only the bubbles which can alter considerably the liquid; the molecules also contribute towards distortion of the bubble pattern as a result of pollution of the anode. We took that into account with frequent cleaning of the wires. As this resulted in a conflict between an undisturbed flow pattern and flow disturbed by the cleaning, we took care to work under optimum conditions. The flow patterns were both photographed and filmed. The film was shot with a speed of 24 or 32 frames s^{-1} .

For pure water, we obtained structures which have already been observed and described¹⁻³ (Figs 2a and 3a). Polyacrylamide solutions (50 p.p.m.) produced a considerably modified sand pattern compared with that produced by pure water, distinguished particularly by the formation of dunes (Fig. 2b). As the interaction between polymer solutions and quartz particles is still not known, it is difficult to explain this phenomenon by one of the various models.

Fig. 3 Hydrogen bubble experiment. a, With tap water; b, with 100 p.p.m. polyacrylamide solution.

This observation suggests, however, that in the turbulent boundary layer of a dilute polymer solution, longitudinal eddy structures were suppressed or deflected from the direction of flow in the immediate vicinity of the bed of a smooth wall.

In the second experiment we again found a thickening of the sublayer in our tests with polymer solutions. It was clearly a transverse eddy formation (Fig. 3b) which dominated the picture.

Although the films would permit some degree of quantitative evaluation the test set-up was not designed so that figures obtained from it would be generally valid. Nevertheless, there is no doubt that the change already perceived visually may be considered as qualitatively established.

It is worth noting that Brennen⁷ observed a transverse wave structure for flow separation at spheres in the case of thin polymer solutions, which points to a similarity of the two phenomena.

Rudd⁸ provided more direct evidence of this change and demonstrated, with laser doppler measurements near the wall, a significant increase in the variation of the velocity components in the direction of flow, whereas practically no difference from pure water could be determined along the pipe axis. Exactly the opposite behaviour was found for velocity fluctuations transverse to the direction of flow; they decreased in comparison with pure water near the wall, but increased in the outer region.

This fact is immediately evident when the variations in the sublayer are derived from eddies moving past, which in the case of the polymer solutions are deflected to a greater extent from their original position in the direction of flow ($u'=0$) into the direction at right angles ($w'=0$).

Similar arguments come from local correlation measurements which, on the basis of their chronological sequence, represent a measure of the frequency of occurrence of a certain eddy structure. Thus, a considerable increase in the degree of correlation is found in the direction transverse to the flow, with a far slower decay of this correlation in the direction of flow⁹.

The appearance of a larger number of transverse eddies is an almost ideal explanation of these measurements. In the direction at right angles to the flow, the movement is strictly influenced by the eddy itself. As a result of the high stability of the eddy structures during transportation by the flow the influence lasts longer⁹.

The thickening of the sublayer also leads to an enlargement of the individual eddy diameter, so that the fundamental change of the flow structure in the sublayer varies from thin longitudinal eddies in pure water to relatively thick transverse eddies in dilute polymer solutions.

To return once more to our work with fine sand, we now understand how a dune structure occurs transverse to the direction of flow. In principle the same as the longitudinal eddy structure, but it is wider because of the thicker sublayer.

This, however, only explains the formation of dunes, not their marked wedge shape, which must be the result of a locally varying transfer process. As the dune bank formed transverse to the flow is eroded at the point where the flow in this sublayer exhibits higher Reynolds stresses, it is natural to consider the sand pattern as a dune formation which is eroded locally by shearing waves.

The pattern itself has a self-stabilising effect, as the shearing waves are channelled by the topography of the sand. The stochastic disturbances which possibly still occur locally and sporadically, and which spread out as shearing waves, are thereby fixed; this results from an interaction with the mobile bed. So no comment can be made about the local stability of the disturbances; only about the relationships between wavelengths in both directions of propagation. This relationship determines the mean direction of propagation of the disturbances and can be found from the characteristic apex angle β . Assuming that these disturbance waves appear in the wedge structure β can be measured (Fig. 2b). For our test, it averaged $14.5 \pm 1.5^\circ$.

Morrison¹⁰ *et al.* specified a disturbance wave model for sublayers and took measurements by frequency wave number spectra on turbulent flow in pipes.

Using shearing velocity and kinematic viscosity as scaling values, they found, expressed dimensionless in these magnitudes, well-defined wavelengths transverse to the flow and very weakly defined wavelengths in the direction of flow. The characteristic angle was 12° .

The sublayer is thickened substantially by the addition of polymers and the disturbances are propagated in the form of shearing waves, which do not differ greatly from those in pure water.

This alteration in structure, as can be demonstrated clearly, indicates that it would be premature to draw speculative conclusions at this stage about the Toms effect itself.

Rather, it needs to be explained why the concentration of vorticity is rotated.

As one of the most obvious explanations lies in associating this behaviour with normal stresses, this indicates an elastic effect.

Lead monolayer lubrication in steel machining studied by Auger electron spectroscopy

ALTHOUGH free-machining steels are widely used in the manufacturing industry because of improved machining characteristics, such as prolonged tool life, the detailed mechanisms by which the additions of lead and manganese sulphide bring this about are subject to debate. We report the existence, on the swarf from leaded free-machining steel, of near monatomic layers of lead which are thought to enhance the lubrication of the swarf-tool interface.

The steel was dry machined at six cutting speeds in the range of 50–350 feet min⁻¹ (0.25–1.78 m s⁻¹) using a new M2 high-speed steel cutting tool for each speed. The cutting tool geometry conformed to the relevant International Standards Organisation recommendation. Samples of the swarf were carefully collected to avoid contamination and were then analysed by Auger electron spectroscopy (AES).

AES is an electron probe technique which gives an elemental analysis of the few uppermost atom layers at a surface. Combined with ion beam etching, AES provides element composition profiles of the surface layers with in-depth resolutions as good as 1 nm. Figure 1 shows a typical spectrum of a swarf surface (air-exposed) which had contacted the rake face of the tool, indicating a very strong concentration of lead and manganese sulphide in the surface layers of the swarf compared with the bulk. The uniform distribution of the lead over the swarf surface is illustrated in the 'Augergraph' in Fig. 2. The lead Auger electron signal has been used as a means of recording the distribution of lead; this resembles the use of X rays in the conventional electron microprobe but here refers more critically to the one-or-two atomic layers nearest the surface. Similar spectra to that in Fig. 1 were obtained from the other side of the swarf which had previously contacted the flank face of the tool.

Further information on the composition of the surface layers of the swarf was obtained by ion beam etching. Figure 3 shows that both carbon and lead were largely removed from the surface in the period of the ion bombardment, whereas manganese remained. The decrease in sulphur concentration is an artefact, attributed to oxidation of manganese sulphide induced by electron beam irradiation in the presence of residual water vapour in the Auger electron spectrometer. This was checked by moving the electron beam to a neighbouring position on the etched surface, thus restoring the sulphur signal to its original value. The ion bombardment was continued

Fig. 1 Auger electron spectrum of the surface of leaded free-machining steel swarf. The swarf surface had contacted the rake face of the tool during machining at a surface speed of 120 feet min⁻¹ (0.61 m s⁻¹). The steel had the following composition: C, 0.10%; Si, 0.01%; Mn, 1.0%; S, 0.30%; Pb, 0.18%; Ni, 0.03%; Cr, 0.01%; Mo, 0.01%; Cu, 0.10%; P, 0.063%; N, 0.004%. The ordinate is a derivative of the electron energy distribution, $n(E)$.

for a total of 1,680 s resulting in further removal of lead, the manganese concentration remaining constant. The profile shows that the surface region of the swarf consists of a series of layers, an outer contamination layer containing carbon, then an extremely thin layer of lead which in turn covers a composite substrate of iron and relatively thick patches of manganese sulphide.

Fig. 2 Scanning electron Auger micrograph (Augergraph) of leaded steel swarf showing uniform distribution of lead (bright areas) on the swarf surface. This structure was obtained by programming the primary electron beam (50 μ m diameter) to describe a raster on the target (as with the scanning electron microscope) and by using the signal from the lead Auger electron peak to modulate the brightness of a video display¹.

The ratio of the observed lead (91 eV) to iron (700 eV) Auger electron peak-to-peak amplitudes ranged from 1.5 to 8.5 for swarfs obtained at cutting speeds between 50 and 350 feet min⁻¹ (0.25 and 1.78 m s⁻¹). The variation in the ratio with cutting speed is the subject of a further investigation. The expected relative peak intensity value for one monolayer of lead on iron is 9.2, calculated from the Auger electron spectra of the pure elements and from measured electron ranges in similar elements^{2,3}. It seems therefore that the lead is concentrated in a layer about one monolayer thick. Further evidence for this localisation is obtained from the shape of the sputtering profile. The predicted profile from sputtering statistics for one monolayer or fraction of a monolayer of lead on iron is of the form $\exp(-nyt)$ where n is the number of argon ions per target atom per second, y is the sputtering yield and t is time¹. Figure 4 shows the observed exponential decrease with ion bombardment time.

To obtain the precise thickness of the lead layer from the profile it is necessary to know the relevant sputtering yield. The appropriate sputtering yield in this case is that for lead from the surface of iron, both elements having been oxidised by air exposure; this yield is not known. It may be expected to differ from the value for bulk lead since Tarng and Wehner⁴ have shown that the sputtering yield of an atom is strongly dependent on the substrate. From the ion beam current density ($n=1.2 \times 10^{-2}$ ions per lead atom per second) a value of $y=0.35$ would be consistent with a monolayer lead level. As expected, this value is lower than the yield for bulk lead since yields are

Fig. 3 Element concentrations normal to the surface of the swarf described in Fig. 1. The profile was obtained by sputtering at normal incidence with 620 V argon ions and monitoring with AES. The Auger electron peaks used were those shown in Fig. 1; in the case of iron and manganese the peaks used are marked with an asterisk. The filled symbols (\blacktriangle and \blacklozenge) on the right of the figure refer to sulphur and lead after moving the electron beam to a neighbouring position on the ion etched surface (see text).

inversely proportional to heats of sublimation⁵, and surface energy measurements indicate that lead adsorbs strongly on the surface of iron⁶.

It is considered that the lead layer is formed on the surface of the swarf during cutting by a process of extrusion due to the high compressive forces in the primary deformation zone. The movement of lead would also be assisted by the high local temperatures generated during cutting. It is important to note that not more than one monolayer of lead is formed on the swarf over the range of cutting speeds investigated. This may be due to the higher binding energy of the first layer of lead atoms to the iron substrate, compared with the second layer of lead atoms to the first.

Fig. 4 Sputter profile normal to the swarf surface for lead relative to iron derived from Fig. 3. The curve is the exponential fit described in the text.

The wear mechanisms relevant to cutting tool wear and tool failure have been reviewed by Tabor⁷, the operative wear mechanisms depending critically on temperature and the properties of tool and workpiece. Wear processes of M2 high speed steel during the machining of a wide range of free-machining steels have recently been studied (S. Akhtar and B. M., unpublished), confirming that the presence of lead in resulphurised free-machining steels gives an additional improvement in cutting tool life above that conferred by manganese sulphide alone. Their study has also confirmed that the principal wear mechanisms in the cutting range 50 to 325 feet min⁻¹ (0.25 and 1.65 m s⁻¹), using high speed steel cutting tools, are adhesive and abrasive wear. It would seem that a layer of lead on the swarf at this surprisingly low monolayer level is sufficient lubricant to give improved tool life by the reduction of adhesive wear. It is known that the equilibrium segregation of a minority species to monolayer levels at grain boundaries leads to reduced grain boundary cohesion⁸ and that lead can induce brittle failure of high strength steels⁹. Similarities may exist in the present reduced adhesion between the swarf from leaded free-machining steel and the tool.

Lattice resolution in an electron-beam sensitive polymer

RECENT developments in our understanding and application of high-resolution defocusing phase contrast electron microscopy have contributed significantly to structural studies of carbon fibres from a range of precursor materials¹⁻⁴. For example, we are now able to follow the natural pattern of carbonisation in the standard commercial process for polyacrylonitrile (PAN)-based carbon fibres, and to detect variations in structure which give rise to abnormal physical properties^{5,6}. One major factor which has influenced the success of the work on carbon fibres is the stability of the stacked carbon ribbons to irradiation by an electron beam, and the relative ease with which the {002} lattice fringes can be recorded. In fibrous organic polymers we have observed massive degradation of structural order as revealed by the rapid deterioration of the electron-diffraction pattern^{7,8}; this has precluded the recording of lattice-fringe images and so prevented the breakthrough in understanding which would undoubtedly follow as a result of direct observation of fibre structure at the molecular level.

Here we report for the first time the direct imaging of crystallite lattice fringes in a beam-sensitive polymer together with a preliminary analysis of diffraction data in terms of crystallite size.

Fig. 1 Electron diffraction pattern from Kevlar 49.

Table 1 Crystallite size in Kevlar 49

Technique	Crystallite size (nm)
X-ray diffraction	7.9
Electron diffraction	8.1
Lattice fringes	8.6-22.5

Recently, E. I. du Pont de Nemours and Co. Inc. have developed the poly-(*p*-phenylene terephthalamide) fibre Kevlar 49 composed of hydrogen-bonded sheets containing phenylene rings, whose mechanical properties approach those of PAN-based intermediate-modulus carbon fibres⁹. A preliminary X-ray diffraction survey indicates that the material is highly crystalline and there is no evidence for the small-angle meridional reflections which are traditionally associated with chain folding in polyamide and polyester

Fig. 2 Micrograph showing 0.433 nm lattice fringes in Kevlar 49 ($\times 3,200,000$).

fibres. Quantitative analysis of the equatorial X-ray diffraction trace by a method of profile resolution developed earlier¹⁰, indicates a crystallite width of 7.9 nm normal to the fibre axis, as obtained from the width of the resolved 0.433 nm reflection. The usual corrections were made to the overall intensity profile obtained by a step-scan diffraction procedure, and, after resolution, the peaks were corrected for instrumental broadening by a Stokes deconvolution method.

For electron-microscope examination in a Philips EM300, fibres of Kevlar 49 were fragmented by ultrasonic irradiation and the resulting material deposited on carbon-coated grids in the usual way. Electron diffraction patterns were

recorded which show a wealth of reflections. The principal diffraction maxima are shown in Fig. 1 where the innermost equatorial and three meridional reflections (even-order layer lines) correspond to Bragg spacings of 0.433, 0.388 nm, and 0.634, 0.317, 0.211 nm, respectively. These reflections decay at different rates during exposure to the electron beam; the 0.433 nm reflection is most stable but does not persist longer than about 120 s at a beam density of 3.28×10^{-4} A mm⁻². The equatorial intensity distribution was obtained from a corrected microdensitometer trace and analysed by a modified profile-resolution procedure developed for electron-diffraction analysis of selected areas in carbon fibres of heterogeneous structure¹¹. In spite of some degradation in the electron beam, the average crystallite size obtained from the breadth of the resolved 0.433 nm reflection is 8.1 nm, a value which compares favourably with the value obtained from X-ray diffraction analysis (Table 1).

Medium-resolution electron micrographs reveal breakdown of the fibres into extensive sheets which exhibit numerous kink bands, and, under dark-field conditions, a dense population of crystallites. Using carefully selected instrumental operating conditions developed from work on other beam-sensitive polymers⁷, high-resolution electron micrographs were recorded at magnifications calibrated by measurement of the 1.194 nm lattice fringes derived from the (201) planes in platinum phthalocyanine crystals. At the appropriate focal level, micrographs of Kevlar 49 clearly show lattice fringes related to the layer planes from which the 0.433 nm equatorial reflection originates; an example is illustrated in Fig 2. Although it must be emphasised that there is no exact one-to-one correspondence between layer planes and lattice fringes, an estimate of crystallite size in a direction at right angles to the fibre axis can be determined directly from such micrographs. Figure 2 shows an array of almost parallel lattice fringes approximately 12.5 nm in width, whereas in other micrographs more disordered lattices are apparent.

Measurement from a number of micrographs gives a size distribution within the range 8.6–22.5 nm (Table 1). It would appear that the averaged values obtained from fragments and fibres of Kevlar 49 are below the range measured directly. This comparison immediately questions the quantitative estimation of crystallite size by the classical diffraction methods, although it is possible that at present our lattice fringes are derived from the more perfect regions of the structure.

In conclusion we believe that the importance of this work is twofold. First, it provides a basis for the elucidation of relationships between molecular structure and physical properties in polymer systems, and second, it should enable us to test the validity of standard diffraction methods used to assess crystallite size and order.

Structure of α -cyclodextrin-*p*-iodoaniline complex

CYCLODEXTRINS, which are cyclic α -1,4-linked D-glucose oligomers, form a number of inclusion compounds with a variety of 'guest' molecules¹. The direct evidences for the formation of inclusion compounds have been derived from NMR spectra² and X-ray studies^{3–5}. α -Cyclodextrin is capable of forming a complex with a bulky molecule whose length is longer than the depth of the cavity of α -cyclodextrin. It is as yet not clear that which part of the molecule is included in and in what manner the molecule is bound to the interior of the α -cyclodextrin ring. We present here the structure of the α -cyclodextrin-*p*-iodoaniline (α -CDx-*p*-IAN) complex, (C₆H₁₀O₅)₆·C₆H₄NI₃H₂O.

The crystal is orthorhombic and the space group is P2₁2₁2₁, with unit cell dimensions; *a*, 13.659 (2) Å; *b*, 15.413 (4) Å; *c*, 24.436 (5) Å. The calculated density with *Z* = 4 was 1.610 g cm⁻³ and the observed density was 1.602 g cm⁻³ (flotation method). Intensities for 5,007 independent reflec-

Fig. 1 The structure of the α -cyclodextrin-*p*-iodoaniline complex. The circles, in order of decreasing size, represent iodine, oxygen and carbon atoms, and the black dots indicate nitrogen atoms.

tions were measured on a Rigaku AFC four-circle diffractometer using graphite monochromatised MoK α radiation ($2\theta \leq 50^\circ$).

The structure was solved by the heavy atom method using 1,171 reflections with $2\theta \leq 30^\circ$. The three-dimensional electron density map calculated on the basis of coordinates of the iodine atom revealed the rough structure of the complex. The least-squares refinement of the atomic parameters which were estimated on the electron density map was unsuccessful. The accurate positions and directions of the six glucose units and the *p*-IAN molecule were determined by the block-diagonal rigid-body least-squares technique³. The O₆ atoms and water molecules were found on a difference Fourier synthesis. In successive refinements, one of the O₆ atoms was found to be disordered. Using 3,519 reflections with $|F_o| \leq 3\sigma(F)$, the final block-diagonal least-squares refinement with anisotropic temperature factors reduced the *R* value to 0.072. Fig 1 illustrates the structure of the complex.

Each glucose unit is in the C1 chair conformation, and all glucose units are α -1,4-linked; this result is in agreement with the structures of the other α -CDx complexes which were determined by X-ray analysis³⁻⁵. The *p*-IAN molecule is included in the cavity along the axis of α -CDx. The iodine atom and the benzene ring are situated in the cavity of α -CDx, while the nitrogen atom lies outside the cavity. The shortest distance between the benzene ring and α -CDx is 3.25 Å which is from an O₄ atom to a carbon atom of the benzene ring. This rather short intermolecular distance indicates that *p*-IAN is rigidly fixed in the cavity. The shortest distance from the iodine atom is 3.70 Å which is the distance to the disordered O₆ atom.

In the α -CDx-*p*-IAN complex, the six O₄ atoms of α -CDx lie very near the least-squares plane of themselves, and the maximum deviation from the plane is 0.13 Å. In the α -CDx-potassium acetate complex³ and the α -CDx-H₂O complex⁴, the maximum deviations are 0.01 Å and 0.98 Å, respectively. The average valence angle of α -1,4-linking oxygen atoms is 120° (2) which is in agreement with 119.1° in the α -CDx-potassium acetate complex and $119 \pm 3^\circ$ in the α -CDx-I₂ complex⁵. The distances between oxygen atoms O₂ and O₃ of adjacent glucose units are 2.68, 2.76, 3.00, 2.92, 2.98 and 2.87 Å which are the acceptable distances for hydrogen bonds. On the other hand, in the α -CDx-H₂O complex and the α -CDx-I₂ complex, there exist distances of 3.36 Å and 3.83 Å, respectively. In the α -CDx-*p*-IAN complex, all C₆-O₆ bonds are oriented to the outside of the cavity and the conformation is the same as that found in the α -CDx-I₂ complex; the conformational angles O₅-C₅-C₆-O₆ are $-75 \pm 8^\circ$ in the α -CDx-*p*-IAN complex and $-70 \pm 8^\circ$ in the α -CDx-I₂ complex.

Is the aardwolf a mimic of the hyaena?

MIMICRY is a phenomenon of evolutionary convergence or parallelism by which an edible mimic species gains some measure of protection from predators by virtue of its close

resemblance to a model species which is unpalatable (that is, distasteful or dangerous)¹⁻³. Predators learn to avoid the unpalatable model species after one or more adverse experiences with it, and any mimic species that resembles the model sufficiently closely will likewise be avoided.

The first examples of mimicry were documented in Brazilian butterflies¹—most additional examples and experimental work have been limited to mimicry in insects. Vertebrates exhibiting mimicry are rare, but include fish⁴, snakes^{5,6} and birds^{7,8}. A single example has previously been described in mammals: Shelford described a series of five squirrel species which mimic unpalatable treeshrew models in Borneo^{9,10}. The case described here is a possible additional example which, if confirmed, extends the phenomenon of mimicry to a large African mammal.

The genus *Hyaena* is represented in Africa today by two species: the striped hyaena, *H. hyaena*, inhabiting northern Africa; and the brown hyaena, *H. brunnea*, limited to southern Africa. Hyaenas (the spotted hyaena, *Crocuta*, excluded) weigh 50–60 kg, and inhabit open dry plains and thorn scrub, live singly or in pairs, and are chiefly nocturnal. *Hyaena* has a sloping back, pointed ears, and an erectile mane. It has strong

Fig. 1 External appearance of, a, the aardwolf, *Proteles cristatus*, and, b, the hyaena, *Hyaena hyaena*, both drawn to the same scale. Redrawn by P. Olsen from colour illustrations in Dorst and Dandelot²⁰.

teeth and jaws and it is known to kill live game occasionally, although it is primarily a scavenger.

The aardwolf *Proteles cristatus* is a much smaller, jackel-sized (12–15 kg) mammal with a discontinuous distribution: a northern population is found throughout most of East Africa, and a separate population inhabits southern Africa. *Proteles*, like *Hyaena*, has a sloping back, pointed ears, and a well developed erectile mane along the dorsal spine from neck to tail. This mane is composed of stiff hairs some 20 cm in length and, when erected, makes the aardwolf appear considerably larger than it actually is¹¹. *Proteles* inhabits open

plains and thorn scrub, lives singly or in pairs, and is chiefly nocturnal. It has only vestigial cheek teeth and feeds largely on termites and other insects, and occasionally on carrion and rodents^{12,13}.

In his initial description of *Proteles*, Geoffroy St-Hilaire¹⁴ noted that its external appearance is very similar to that of *Hyaena*, a resemblance noted in virtually every subsequent description of the aardwolf (Fig. 1). Kruuk¹³ observed that *Proteles* and *Hyaena* look so similar that they are often confused. The resemblance of *Proteles* to *Hyaena* in body, mane and tail colour, and in the colour and development of stripes remains close in spite of considerable clinal variation in these characters; the pattern in each subspecies of *Proteles* resembling closely the sympatric subspecies of *Hyaena*¹⁴⁻¹⁶. Size is the only real difference in the external morphology of the two, and this is a notoriously difficult quantity to perceive in the field in the absence of some fixed comparative scale.

In addition, *Proteles* is found throughout its distribution in the same open plain or thorn scrub habitat as *Hyaena*, and its general behaviour is remarkably similar. The aardwolf and hyaena are both chiefly nocturnal, and live singly or in pairs. Even their kneeling defensive response to attack is similar¹¹.

The external similarity of *Proteles* to *Hyaena* extends also to most of the characters of internal anatomy that have been studied, indicating that *Proteles* is closely related to the hyaenas. The chromosomes¹⁷⁻¹⁹ and haemoglobin mobility²⁰ of *Proteles* are virtually identical to those of *Hyaena* and *Crocota*, and the gyri and sulci of the cerebral hemispheres of the brain are arranged on exactly the same plan¹¹. The complete dental formula of *Proteles*, though not always fully developed, is the same as that of *Hyaena* and *Crocota*²¹. The male reproductive tract of *Proteles* appears to be more similar to that of *Hyaena* than to that of *Crocota*^{11,22}. *Proteles* differs from *Hyaena* principally in having a dentition much reduced in size, and in retaining the pollex (a digit lost in both *Hyaena* and *Crocota*)²³.

The evolutionary lines leading to *Hyaena* and *Crocota* appear, from the fossil record, to have been distinct since the Miocene²⁴. Fossils bearing on the evolution of the aardwolf have recently been discovered^{21,25} which indicate a Pliocene or earlier time of divergence of *Proteles* from the ancestral hyaenid stock, but the precise phylogenetic relationships among these three genera of Hyaenidae are not yet completely clear.

Two hypotheses of hyaenid relationships seem tenable. *Proteles* may have separated from the common ancestor of *Crocota* and *Hyaena* before they separated (suggested by the shared loss of the pollex in the latter two genera), in which case the close external resemblance of *Proteles* to *Hyaena* is perhaps convergent. On the other hand, *Crocota* may have separated from the *Proteles*-*Hyaena* stock before these two became differentiated (suggested by the reproductive tract and the close external resemblance), in which case the external resemblance of *Proteles* and *Hyaena* may reflect a parallel retention from a common ancestor having this appearance.

The nearly complete geographic sympatry, close external resemblance, and similar behaviour of *Proteles* and *Hyaena* are unusual in closely related forms, since speciation normally involves significant divergence in geographic distribution, in external appearance, or in behaviour. All of the conditions of Batesian mimicry are met by *Proteles*, and this may help to explain its distribution, appearance, and behaviour. Only the predator remains to be identified.

Leopards occur throughout the range of *Proteles*, they are most active at night, and they are predominantly visually oriented predators. Leopards routinely prey on jackals^{26,27} and, in view of their wide prey tolerance²⁸, might be expected to prey on *Proteles* as well. Because of its large size and strong skull, a *Hyaena* would be dangerous to an attacking leopard. The much smaller, weaker *Proteles* would be a poor match for a leopard, and it seems that an important component of the aardwolf's defence against predators may be its close external resemblance to the larger, more dangerous *Hyaena*. The ability of *Proteles* to erect its mane when excited would

further confuse a potential predator as to its actual size and identity.

This possible case of mimicry in a large mammal is unique, and deserves further investigation. Unfortunately, low population densities and nocturnal activity patterns make both *Proteles* and *Hyaena* difficult to study in the field. Additional study of their behaviour and ecology will be of great interest, and observation of any interactions with leopards of particular importance.

Total human body protein synthesis in relation to protein requirements at various ages

THE intensity of body and tissue protein metabolism per kg declines with increased adult body size in mammals¹. This fall parallels a similar progressive decline in the intensity of energy metabolism²⁻⁴. It has also been concluded that protein metabolism per unit of body weight is about four to five times faster in young rats than in adult man¹; this pattern of change extends to cellular and subcellular aspects of protein metabolism, such as plasma albumin synthesis, liver RNA content and enzyme activity^{1,5}. Similarly, the rate of protein synthesis per kg total body weight declines during growth and development within a species, such as the rat⁶. This parameter again parallels the reduction in the intensity of energy metabolism which occurs during the growth period³.

Such surveys provide a general picture of protein metabolism in mammals and help to explain the metabolic basis for differences in dietary protein requirements both within and between the various species. The concepts involved should apply to man at various ages⁷⁻⁹. In previous studies with human subjects, however, different approaches have been used, some of which are no longer considered valid, and insufficient detail has been provided. It is therefore difficult to use the estimates to compare changes in body protein and energy metabolism with those for dietary protein needs throughout a man's life.

Using a common approach, we have tried to characterise the relationship which exists between protein and energy metabolism in man and to examine dynamic aspects of body protein metabolism with reference to dietary protein needs, during the period of rapid growth and development and the later years when senescence dominates body metabolism and function. The procedures, analytical methods and calculations of total body

protein synthesis have been described previously (refs 11, 12, and W.P.S., P.B.P., R. S. Goldsmith, N.S.S., and V.R.Y., unpublished). To quantitate the rate of total body protein synthesis we used a modification of the constant isotope method¹⁰, which is based on the continuous administration of ¹⁵N-labelled glycine and the analysis of urinary urea for ¹⁵N after a constant level of isotope enrichment has been achieved. The main difference in our experiments was that equal tracer levels of ¹⁵N-glycine were given orally at intervals of 3 h, rather than by continuous intravenous or intragastric infusion. We found that these two methods of infusion (continuous and at

Table 1 Total body protein synthesis rate in humans at various ages

Age group	No. of studies	Body weight (kg)	Age (range)	Total body protein synthesis (g kg ⁻¹ d ⁻¹)
Newborn (premature)	10	1.94±0.59	1-46 d	17.4±7.9
Infant*	4	9.0±0.5	10-20 months	6.9±1.1
Young adult	4	71±15	20-23 yr	3.0±0.2
Elderly	4	56±10	69-91 yr	1.9±0.2

*For comparative purposes, the data of Picou and Taylor-Roberts¹⁰ have been included.

intervals) give essentially identical estimates of total body protein synthesis. ¹⁵N-glycine (95 or 99 atoms per cent excess) was administered at a rate of 0.5 mg ¹⁵N per kg body weight per day, given during a 60-h tracer period in studies with young adults and the elderly.

Three age groups were studied. (1) Newborn, including six premature infants and one full-term baby. All were studied during a 30-36 h ¹⁵N tracer period within 1-45 days of life. One baby was studied at 1 and 13 days of age and another at 16, 31 and 45 days of age. (2) Healthy, normal young adults, three male and one female, 20-23 yr old. (3) Healthy, elderly women, 69-91 yr of age. Diets provided constant intakes of essential nutrients judged to be adequate for each age group. A more detailed description of the subjects, experimental details and diets will be published elsewhere. Urinary urea was isolated¹³ and analysed for ¹⁵N, following reaction with hypobromite¹⁴, with the aid of a dual collector, isotope ratio mass spectrometer (MS 11, Vacuumetrics, Waltham, Massachusetts).

Table 1 summarises results for body protein synthesis for the three age groups studied. The intensity of body protein synthesis declined rapidly during the first year of life, the rate in young adults being about one sixth that in premature infants. During later adult years protein synthesis (per unit of body weight) continued to decline but more gradually, the value for elderly subjects being 63% that for young adults. The differences among the older age groups reflect, in part, body compositional differences but this could not account for the marked decline in the synthesis rate between premature babies, full-term infants and young adults. Thus, as observed in experimental animals⁶ the intensity of protein metabolism in man declines throughout life.

To explore further the relationship between changes in the intensity of whole body protein synthesis and in energy metabolism we have recalculated the data on the basis of energy expenditure for each age group. For the prematures total energy intake was used for the calculation; for comparing adults, it was considered appropriate to use the basal metabolic rate. The results are summarised in Table 2. Differences observed in the intensity of protein metabolism among the various age groups (Table 1) are essentially eliminated when body protein synthesis is related to the energy expenditure for the different age groups (Table 2). These results confirm previous observations that protein metabolism is closely related to basal energy metabolism both within and between mammalian species^{1,4}.

Finally, the nutritional significance of these observations on whole body protein synthesis may also be assessed by comparing changes in dietary protein needs at various ages with decline in the intensity of whole body protein metabolism. The comparison

Table 2 Mean total body protein synthesis in relation to energy metabolism and Dietary protein allowances in premature babies, infants, young adults and elderly women

Age group	Dietary protein allowance* (g kg ⁻¹ d ⁻¹)	Protein synthesis (g (per caloriet) (per g protein allowance)
Newborn (premature)	3.2	0.15±0.09†
Infants§ (~1 yr)	1.3	5.3
Young Adult	0.57	0.11±0.01
Elderly	0.42	0.11±0.03

*Values for prematures are based on mean protein intake by the babies studied. Allowances for infants and young adults taken from FAO/WHO¹⁵ and for the elderly the allowance is based on the same method of estimation using unpublished data (W. D. Perera), on determined obligatory urinary and faecal nitrogen losses for these four subjects.

†Energy expenditure for prematures based on total energy intake. For young adults the values for basal metabolic rate were obtained by calculation from Altman and Dittmer¹⁶. In the elderly group basal metabolic rate was determined by indirect calorimetry.

‡Mean ± s. d.

§Values for protein synthesis taken from Picou and Taylor-Roberts¹⁰ for this age group.

provided in Table 2, using current estimates for daily protein needs¹⁵, shows a fall in the latter which parallels that for total body protein synthesis with progressive growth and during subsequent ageing. Hence, the amount of utilisable protein required to support body protein synthesis does not show a marked age-dependent change in man when needs are related to protein synthesis. Our data indicate that approximately 1 g of dietary protein is required to support the needs for 4 to 5 g of total body protein synthesis. This suggests that the efficiency of total dietary nitrogen utilisation is similar in the newborn, adult and elderly, and that the differences in protein needs, expressed per kg body weight, for the various age groups are related to differences in the amount of protein synthesised per unit time.

This conclusion may also apply equally to the individual dietary essential amino acids, except during the early neonatal period when histidine¹⁷ and cystine¹⁸ appear to be required as obligatory constituents of the diet because the enzymes responsible for endogenous synthesis, at rates commensurate with metabolic needs, have not fully matured.

These studies were supported by grants from the United States National Institute of Health. We thank the nursing staff of the MIT Clinical Research Center, Dr H. Zayas-Bazan and Miss Christine Bilmazes for their help and the subjects for their cooperation. (In addition to administrative approval of the Committees on the Use of Humans as Experimental Subjects of the Boston Hospital for Women and MIT, written informed consent was obtained from each baby's parents and the older subjects provided their written informed consent.) The help given by Dr William Cochran, Mrs Joyce Sylvester and the nursing staff of the Special Care Nursery at the Boston Hospital for Women during the studies with premature infants is appreciated.

Mechanisms of cell fusion

We report new findings on the chemically-induced fusion of hen erythrocytes and discuss possible ways in which the lipid and protein/glycoprotein components of membranes may behave during the process of membrane fusion. Our observations are consistent with Poste and Allison's¹ idea that the aggregation of intrinsic membrane proteins is important in membrane fusion but we suggest that fusion may occur in regions of perturbed lipid bilayer which are thus denuded of intramembranous particles.

The intramembranous particles of unfixed T and B mouse lymphocytes have recently been reported to aggregate on incubation at 0°C in dimethyl sulphoxide (DMSO) or 25-50% glycerol²; glycerol-induced aggregation of membrane-intercalated particles has also been observed in *Entamoeba histolytica*³. To test Poste and Allison's hypothesis, we have therefore studied the effects of these agents on hen erythrocytes to determine whether they induce these cells to fuse. On incubation for 5 min at 37°C with 5 M DMSO (35%), the cells became spherical and binucleate cells were observed after 25-30 min. The number of fused cells and the number of nuclei per cell both increased on further incubation (Fig. 1). No fusion occurred on incubation for 45 min with 3 M (or lower concentrations of) DMSO. We anticipated that DMSO would cause cell fusion because it causes the formation of large membrane blisters devoid of intramembranous particles in lymphocytes². The plasma membranes of fibroblasts treated *in vitro* with oleylamine also blister away from the underlying cytoplasmic organelles, and their plasma membranes usually fuse in these regions⁴.

Stewart and Turner⁵ have previously reported, although without comment, an apparent fusion between pairs of human erythrocytes observed in electron micrographs of cells treated with 40% glycerol. In our experiments multinucleated cells were observed on incubation of hen erythrocytes for 22 and 5 h at 37°C in modified Eagle's basal salt medium at pH 7.4 (ref. 6), containing Dextran 60 C (80 mg ml⁻¹) and glycerol (1.5 or 2.5 M, respectively). Dextran 60 C facilitated fusion induced by these quantities of glycerol but in control incubations without glycerol the dextran was not in itself fusogenic⁶. In the absence of dextran most of the glycerol-treated erythrocytes became swollen and were then lysed: only a few cells fused. Fusion induced by DMSO and glycerol, like that induced by fusogenic lipids⁶ was calcium-dependent (1.8 mM Ca²⁺) and was inhibited by EDTA (5 mM).

Since glycerol causes cell fusion, other polyols have been

investigated for fusogenic properties. Sorbitol fuses hen erythrocytes, numerous multinucleated cells being present after 2 h incubation in 2.5 or 3 M sorbitol dissolved in the standard buffer (free from Dextran 60 C). Higher and lower concentrations of sorbitol were less effective. Multinucleated cells have also been observed with mannitol (1.25 M, 6 h incubation), ethylene glycol (20%, 5 h incubation) and sucrose (1 M, 5 h incubation). The non-fusogenic Dextran 60 C (molecular weight approximately 90,000) greatly facilitated fusion by sucrose. In contrast, long incubation (30-48 h) of the cells

Fig. 1 Light micrographs ($\times 672$) of hen erythrocytes: a, cells (approximately 3.5×10^8 cells ml⁻¹) incubated at 37°C at pH 7.4 in Eagle's basal salt solution buffered with sodium cacodylate⁶; b, cells incubated in the buffer for 30 min at 37°C with 5 M dimethyl sulphoxide (DMSO), showing the cell adhesion which precedes cell fusion (double arrow) and three binucleate cells (single arrows); c, a multinucleated cell after incubation for 90 min as in b. Nomarski differential-interference-contrast microscopy.

with 80-100 mg ml⁻¹ of a high molecular weight dextran (2×10^6) was itself capable of yielding many multinucleated cells. Polyethylene glycol (molecular weight 6,000), which has recently been shown to fuse plant protoplasts⁷, is also capable of causing extensive cell fusion with hen erythrocytes.

Aggregation of membrane proteins may occur either by disorganising membrane lipids with a micellising agent such as lysolecithin⁸, or by increasing the fluidity of membrane lipids by heating⁹, or by the insertion of a low melting fatty acid or ester⁶. Whether glycerol induces protein clustering by interacting with the lipids or the proteins of membranes is problematic. The addition of glycerol to a lipid film at an air-water interface will, however, lower the surface potential of a condensed or an expanded film and also further expand a partially-expanded film¹⁰.

Poste and Allison¹ indicate that complete fusion of membranes, as observed in cell fusion, may be regarded as an extension of partial fusion observed in intercellular junctions. Particle aggregation in junctions presumably involves stable intermembranous protein-protein interactions as well as intramembranous protein clustering. In contrast, only the latter may be significant in membrane fusion, and protein clustering may be followed by lipid-lipid interactions between membranes, leading to a loss of membrane individuality and allowing membrane fusion to proceed. This interpretation is consistent with the fact that sonicated protein-free phospholipid vesicles can fuse readily under specified conditions¹¹⁻¹³.

Whether or not endogenous enzymes (for example, lipase¹⁴) are involved in one or more stages of chemically- or virus-

Fig. 2 Possible relationships between the lipid molecules and the intrinsic proteins of biological membranes during membrane fusion: *a*, two membranes in close proximity which do not fuse because the proteins of the membranes are randomly arranged in their respective lipid bilayers; *b*, membranes in which fusion may now proceed, by the interaction and intermingling of their lipid molecules, after the emergence of protein-free areas of lipid bilayer as a result of aggregation of the intrinsic proteins in both membranes. Compared with *a*, the lipid molecules of the membranes that are about to fuse have been perturbed; the lipids of *b*, are either more fluid (as illustrated), or, in the extreme case, are rearranged in micellar form (not shown).

induced cell fusion remains debatable. We suggest therefore that cell fusion induced by exogenous chemical agents seems to involve, *inter alia*, the following events. First, a perturbation of the bilayer structure of membrane lipids may occur which increases the fluidity of the lipid region, or in the extreme case results in micelle formation. These changes in the lipid structure of the plasma membrane then allow the aggregation of intramembranous protein/glycoprotein particles. Second, the interaction and intermixing of the disturbed lipid molecules of closely apposed membranes in regions denuded of intramembranous proteins and glycoproteins may allow adjacent cells to fuse (Fig. 2). Concanavalin A, polylysine and protamine, which have been reported to induce aggregation of membrane proteins, cause erythrocytes to aggregate but not to fuse. In some instances, however, the induction of protein clustering may be sufficient to lead to fusion (such as that of *Drosophila* cells induced by concanavalin A, ref. 15), if aggregation of the proteins gave rise to perturbed, rather than stable, pools of lipid bilayer.

Comparable mechanisms to that suggested here may apply to fusion involving the membranes of subcellular organelles. For example, during mucocyst secretion by exocytosis in *Tetrahymena*, fusion occurs between a region of plasma membrane, sequestered within a rosette of particles, and a smooth area of mucocyst membrane free from particles¹⁶. The complex sequence of changes observed in mucocyst secretion may therefore be a specialised means of allowing the lipid bilayers of closely apposed membranes to interact in regions denuded of intramembranous proteins.

Infection of differentiating muscle cells with influenza and Newcastle disease viruses

REPLICATION of influenza viruses is believed to require functions provided by the host cell nucleus because first, influenza replication is inhibited by actinomycin D and α amanitin, which prevent transcription of complementary RNA from virion RNA in the first few hours following infection¹⁻⁴; and second, migration of viral proteins between host cell cytoplasm and nucleus occurs during the virus replicative cycle⁵⁻⁸.

We therefore examined the replication of influenza viruses in skeletal muscle cells, as the latter undergo a characteristic differentiation resulting in the formation of syncytial myotubes, the nuclear DNA synthesis of which has terminated^{9,10}, and the RNA metabolism of which has changed considerably¹¹⁻¹⁴. Such myotubes have been reported to be resistant to direct infection by the DNA viruses polyoma and SV40 (ref. 15) and the RNA Rous sarcoma virus¹⁶, all of which interact with host nuclear DNA during their replication.

Breast muscle from 12-d chick embryos was treated with trypsin and cells were cultured in 60 mm Petri dishes as previously described¹⁷. The appearance of uninfected cell cultures during the course of differentiation is illustrated in Fig. 1. One day after plating, cultures contained predominantly dividing single cells, myoblasts (Fig. 1a), and low frequency myotube formation was also observed. This was followed one day later by a period of rapid cell fusion, which had ceased by about 40 h after plating. If carefully selected batches of horse serum were employed, about 70 to 80% of the myoblasts fused (Fig. 1b). After plating for 3 d the myotubes broadened and areas between myotubes filled with a population of single cells which had failed to fuse (Fig. 1c). The myotubes later became striated, and started contracting spontaneously (not shown).

Influenza virus strain A/AA/6/60(H2N2) was studied, using Newcastle disease virus (NDV) as control, as NDV is not believed to require any host nuclear genetic information for its replication (reviewed in ref. 18). Both viruses were passaged in chicken eggs, and virus seeds received were similarly propagated initially in the allantoic cavity of eggs. Subsequently, the viruses were grown in monolayers of primary chick kidney

cells¹⁹ to obtain tissue culture-grown virus stocks which were used to infect muscle cell cultures.

For infection of muscle cell cultures the growth medium was removed, cells were washed twice with Hanks' balanced salt solution (HBSS) and 1 ml of inoculum added. After 30 min adsorption at room temperature and removal of residual inoculum by washing twice with HBSS, growth medium containing 5% horse serum added. Cultures were incubated at 40°C, and examined for cytopathic effect and also for their ability to adsorb chicken red blood cells (haemadsorption).

Fig. 1 Kinetics of myotube formation in cultured chicken skeletal muscle cells. *a*, Single cells present in prefusion culture 25 h after plating. *b*, Syncytial myotubes and residual single cells in post-fusion cultures 40 h after plating. *c*, Enlarged myotubes and residual single cells 60 h after plating. Small refractile cells in each case are residual chicken red blood cells after these uninfected cultures were tested for haemadsorption.

Fig. 2 Lack of influenza replication in prefusion muscle cell cultures. Cultures of skeletal muscle cells were infected 17 h after plating with influenza virus A/AA/6/60(H2N2) or NDV (La Sota) at a multiplicity of 5 to 10 EID₅₀ per cell. After infection for 9 h, cultures were flooded with a suspension of chicken red blood cells, and 10 min later unadsorbed red blood cells removed by gentle washing. *a*, HAD⁻ appearance of culture infected with influenza virus. *b*, Culture infected with NDV having many HAD⁺ single cells and early myotubes. Several identified fields were examined before and after haemadsorption, thereby confirming that many of the HAD⁺ single cells were of myoblast type. Similar results to those shown in the figure were obtained using multiplicities of infection ten times greater.

Figure 2 shows cultures infected with influenza and NDV when observed for haemadsorption 9 h after infection. With the former, very few, if any, single cells were haemadsorption-positive (HAD⁺) in contrast to the NDV cultures where a large proportion of single cells and early myotubes were very strongly HAD⁺. Very similar qualitative findings were obtained in cultures 24 h after infection (not shown).

Table 1 shows this difference in ability of the two viruses studied to replicate in prefusion muscle cells. At 9 h after infection with influenza virus 2% of the cells could be scored as HAD⁺, compared with 1.4% for the control cultures; 24 h after infection with influenza virus 0.8% of the cells could be scored as HAD⁺, compared with 0.26% for the control cultures. It is difficult to interpret this slight difference between values for control and infected prefusion cell cultures as a result of virus replication, in view of the uncertainty with which clusters as small as three red blood cells may be unequivocally identified, and the possibility that small amounts of residual virus from the initial inoculum might cause low levels of haemadsorption. From the results in Table 1 we conclude that any replication of the influenza virus in myoblasts was at best marginal.

Table 1 Efficiency of infection of prefusion muscle cell culture by influenza and Newcastle disease viruses (NDV)

Virus	Time after infection (h)	Total cells	HAD ⁺ cells	% Cells HAD ⁺	% Cells HAD ⁺ , difference from control
None (= control)	9	440	6	1.4	—
None (= control)	24	390	1	0.26	—
Influenza virus A/AA/6/60	9	450	9	2	0.6
Influenza virus A/AA/6/60	24	640	5	0.78	0.52
NDV (La Sota)	9	380	190	50	48.6
NDV (La Sota)	24	420	110	26	25.7

Cells infected with 5 to 10 EID₅₀ of virus were incubated for the time shown before examination for haemadsorption. Each result shown is the total from three or four fields, examined in two separate experiments. Cells were scored as HAD⁺ if they were associated with clusters of three or more red blood cells. Control cells were included to provide a baseline, as small clusters of red blood cells were observed at low frequency in control cultures.

In contrast, NDV exhibited a very significant degree of replication in myoblasts; 9 h after infection 50% of the total cells were HAD⁺ ($P < 0.001$, compared with control or influenza-infected cultures). It should be emphasised that for calculations in Table 1 each myotube was scored as a single cell, although the syncytial cell had been formed by the fusion of some 10 to 20 myoblasts. Accordingly the efficiency of infection calculated for NDV is probably an underestimate, being biased by the fact that the HAD⁺ early myotubes in the cultures were scored

as single cells. Reduction in the proportion of HAD⁺ cells in cultures infected with NDV by 24 h after infection (Table 1) may therefore be an artefact resulting from the increasing degree of cell fusion that occurs in the cultures with time. Even without taking this factor into account, the results in Table 1 show that the efficiency of replication by NDV in myoblast cultures is at least 50 to 80 times greater than for the influenza virus. This has been confirmed by dose-response experiments (M.C.O'N., and A.P.K., unpublished).

We also examined replication by the myxoviruses in post-fusion muscle cell cultures, and for this purpose cultures were maintained without infection until myotube formation had reached its maximum. Infection with influenza virus and NDV was then performed in an identical manner to that employed with prefusion cell cultures. Figure 3a illustrates the high frequency with which myotubes supported influenza virus replication. When cultures were examined about 9 h after infection; virtually every myotube was HAD⁺, whereas of the single cells still present in the culture less than 5% were HAD⁺. Many myotubes and single cells were also HAD⁺ in post-fusion cultures infected with NDV (Fig. 3b).

Similar post-fusion cell cultures were maintained for 24 h after infection with influenza virus or NDV. In this case, influenza virus infected cultures were almost totally devoid of myotubes, which detached from the cell layer, and were observed floating in the culture medium. Since it had been shown that myotubes were infected with influenza (Fig. 3a) it was concluded that prolonged incubation of myotubes after influenza infection resulted in a cytopathic effect and probably cell death. This was supported by the observation that, in post-fusion cultures examined 24 h after influenza virus infection, a few remaining myotubes were strongly HAD⁺ and were beginning to detach from the surface of the culture dish (Fig. 4a). The almost total lack of myotubes 24 h after influenza virus infection is clear from comparisons either with uninfected control cultures of similar age (for example, Fig. 4c); or with similar cultures infected with the lentogenic NDV, which did not cause myotube death by 24 h after infection (Fig. 4b).

These observations establish for the first time that, unlike those viruses which require cellular DNA synthesis for their replication, the RNA viruses of influenza and Newcastle disease can directly infect myotubes of cultured chicken skeletal muscle, in which the cells have terminated DNA synthesis^{9,10}. In addition, under the conditions described, it was demonstrated that, before syncytia formation, cultured muscle cells are inefficiently infected by influenza virus, based on the inability to detect synthesis of the viral haemagglutinin.

Lack of influenza replication in the prefusion muscle cells is unlikely to be an artefact of the multiplicity of infection or host-adaptation compared with NDV. Experimental conditions were identical for pre- and post-fusion cell cultures, the single exception being the state of cellular differentiation. Multiplicities of infection were similar for the influenza and Newcastle disease viruses, and the observations reported were highly reproducible using several different batches of tissue

Fig. 3 Detection of virus growth in post-fusion muscle cell cultures. Conditions were similar to Fig. 2, except that cell cultures were not infected until 40 h after plating, by which time maximum formation of myotubes had occurred. *a*, Culture infected with influenza virus and containing myotubes which were almost all HAD⁺, whereas residual single cells were HAD⁻. *b*, Cultures infected with NDV and containing HAD⁺ single cells and myotubes.

culture-grown virus, although it is not yet known whether the same behaviour holds true for other strains of influenza.

The observation that the state of cellular differentiation can

Fig. 4 Cytopathic effect of influenza virus on myotubes in cultured muscle cells. Conditions were similar to Fig. 3a and b, except that infected cultures were maintained for 24 h before testing for haemadsorption. *a*, Cultures infected with influenza virus, virtually devoid of all myotubes, but which contains an occasional HAD⁺ myotube, showing early cytopathic effect and also beginning to detach from the cell sheet. Single cells are HAD⁻. *b*, Culture infected with NDV, and containing HAD⁺ myotubes and single cells. *c*, Control culture.

affect the ability of muscle cells to support replication of an influenza virus is novel. Since orthomyxoviruses and paramyxoviruses both initiate infection by attachment to sialic acid-containing receptors on cell membranes followed by fusion of virus and cell membranes²⁰⁻²², it seems improbable that the low efficiency with which the influenza virus infected myoblasts was the result of a cell surface restriction. The different behaviour of NDVs and influenza viruses suggests rather that the restriction on influenza virus replication observed in myoblasts was related to functions in the host cell nucleus. That this restriction ceases after myotube formation might well be one result of the changes that occur in the nuclear activities of the muscle cells at the time of myoblast fusion. Further experimentation is required to justify this hypothesis; if valid, the system we have described should prove valuable in studying the role of the host cell nucleus during influenza replication, and the nature of changes in the muscle cell nucleus during differentiation.

We thank Janet Myers for the technical assistance. Seed of influenza virus was obtained from Dr H. F. Maassab of the University of Michigan School of Public Health, and the lentogenic Newcastle disease virus strain La Sota from Dr M. Bratt of the University of Harvard Medical School.

The reversal of methotrexate toxicity by thymidine with maintenance of antitumour effects

METHOTREXATE (MTX) is effective in the treatment of acute lymphoblastic leukaemia¹, choriocarcinoma², Burkitt's lymphoma³, and a number of other solid tumours⁴⁻⁶. An increased therapeutic index for methotrexate with delayed citrovorum factor (CF) has been reported in experimental tumour systems⁷ and in patients with head and neck cancer⁸ and osteogenic sarcoma⁹. The biological basis for this increased therapeutic index is not known, but delay in administration of citrovorum factor is a crucial feature. We have studied the effects of thymidine (TdR) on the toxicity and therapeutic effect of MTX in mice bearing leukaemia L1210. CF was included in the experiments as a positive control, and allopurinol because this drug has been reported to impair the antitumour effects of MTX⁹.

L1210 Leukaemic cells (10⁵) were injected intraperitoneally into BDF₁ male mice, and MTX, CF, TdR, or allopurinol injected intraperitoneally at least 24 h after the inoculation of leukaemic cells. The animals were weighed

Table 1 The effect of thymidine and citrovorum factor in methotrexate toxicity in normal mice

	Drug	Dose (mg kg ⁻¹)	Schedule	No. of deaths/No. of mice	Day of death
Expt 1	MTX	200	qd × 1	1/8	8
		250	qd × 1	7/8	7 ^a
		300	qd × 1	6/8	5,6 ^a
	TdR	500	tid × 4	0/8	—

		500	tid × 4		
	MTX TdR	250	qd × 1	1/8	6
		500	tid × 4		
	MTX TdR	250	qd × 1	5/8	6 ^a ,7
		500	tid × 4		
Expt 2	MTX	300	qd × 1	1/8	7
		400	qd × 1	4/8	7 ^a ,8
	TdR	500	tid × 3	0/8	—
	MTX TdR	300	qd × 1	0/8	—
		500	tid × 3		
	MTX TdR	400	qd × 1	0/8	—
		500	tid × 3		
	MTX CF	400	qd × 1	0/8	—
		500	bid × 3		

The first dose of CF or TdR in combination experiments was given at the same time as MTX.

qd × 1 = once.

tid × 3(4) = 3 times per day for 3(4) days.

Superscript numbers, number of animals dying.

weekly and observed for toxicity and survival. Since animals dying of drug toxicity died before the leukaemic control animals, this allowed the distinction between toxic and tumour deaths to be made⁷.

Table 1 shows that TdR (500 mg kg⁻¹ intraperitoneally three times per day for 4 d), the first dose being given at the same time as MTX, substantially reduced MTX toxicity in normal animals. Figure 1 shows that TdR similarly prevented MXT toxicity in tumour-bearing animals but did not inhibit the antitumour effects of MTX; if allopurinol was added to the MTX-TdR combination, the life of tumour-bearing animals was not prolonged. If the first TdR administration was delayed for 12 h after MTX treatment, the selective rescue effects of TdR were still observed,

and the therapeutic effect was superior to that produced by delayed CF administration. TdR pellets implanted subcutaneously also protected normal tissues from MTX toxicity although the antitumour effects were not inhibited (ref. 10 and M.H.N.T., B.L.B., and E.F., unpublished).

These experiments indicate that in mice TdR prevents MTX toxicity in normal host tissues but does not inhibit its antitumour effects. MTX-TdR seems to be superior to MTX-CF in the treatment of animals with L1210 leukaemia. The biological basis for these observations has not been established. The data suggest that MTX treatment causes thymidylate starvation in normal tissues, which can be reversed by the administration of excess TdR; and since the tumour is not rescued by thymidine, it is possible that

Fig. 1 The effects of MTX, TdR, CF and allopurinol in L1210 leukaemia. Histogram of median survival of control and drug-treated animals. The numbers of animals in each group was at least six, and the first administration of drug was 24 h after intraperitoneal transplantation of 10⁵ ascites cells. MTX was given as a single injection; TdR (500 mg kg⁻¹ three times per day for 3 days) was given at the same time as MTX, alone, with allopurinol, or the first dose was delayed for 12 h after MTX (TdR₁₂). Citrovorum factor (200 mg kg⁻¹) was given at the same time as MTX or the first dose was delayed for 12 h (CF₁₂). MTX caused no significant increase in survival time. MTX-TdR (simultaneous and delayed) at all doses caused significant increase in survival time over control ($P < 0.0001$). MTX-TdR and allopurinol was significantly less effective than MTX-TdR alone: at MTX 200, 250, 275 mg kg⁻¹, $P < 0.001$; at MTX 300 mg kg⁻¹, $P < 0.05$ (Mann-Whitney tests). Methotrexate sodium (4-amino-N¹⁰ methyl pteroylglutamic acid sodium), and citrovorum factor (5-formyl tetrahydrofolic acid, calcium leucovorin) were obtained from Lederle Labs, Pearl River, New York. Allopurinol (4-hydroxy-pyrazolo (3,4-d) pyrimidine) was obtained from Burroughs Wellcome, London and TdR from Nutritional Biochemical Corp.

MTX causes additional disturbances in tumour tissues. Hryniuk¹¹ has reported that MTX causes death in rapidly proliferating L5178Y cells in culture as a result of a lack of purine. Grindey and Moran⁹ observed that allopurinol, which elevates plasma and tissue purine levels, reduced the antitumour effects of MTX in mice with L1210 leukaemia. All these data indicate that MTX treatment may cause purine starvation in L1210 tumour cells *in vivo*. The retention of non-dihydrofolate reductase protein by MTX-Sepharose indicates that MTX may have multiple sites of action¹². It is known, however, that reduced folates are 1 carbon donors in thymidylate and *de novo* purine biosynthesis. As bone marrow cells utilise predominantly pre-formed purines synthesised by the liver¹³, for nucleic acid synthesis it seems possible that TdR may rescue normal proliferating host tissues, which do not rely on *de novo* purine biosynthesis, but not rescue tumour cells in which *de novo* biosynthesis may be the major source of purines.

Microsomal enzyme induction by methadone and its implications on tolerance to methadone lethality

MANY investigators have sought to explain narcotic tolerance as a result of increased metabolic inactivation of the drug. No evidence for disposition tolerance has yet been reported, however¹⁻⁶. On the contrary, tolerance to most narcotic effects seems to be adaptive or cellular tolerance, that is a decrease in pharmacological effects even when enough drug is in contact with target cells in the brain to produce marked effects in naive animals⁷. We wish to report, however, that metabolic inactivation of methadone, a widely used synthetic narcotic, does increase, with a resulting tolerance to its toxic properties.

Subcutaneous or oral administration of methadone has been shown to prevent one sign of narcotic withdrawal in

mice tolerant to and dependent on morphine after implantation of a morphine pellet for 3 d (ref. 8 and L. M., unpublished). After 6 d of oral methadone treatment (100 mg kg⁻¹ of the hydrochloride salt), these mice display tolerance to the lethal effects of methadone, but not to those of morphine (Table 1). This observation suggests the existence of disposition tolerance to methadone, as an increased LD₅₀ for morphine, as well as methadone would have been expected had cellular tolerance developed in these animals.

The liver seems to be the chief site of metabolism for methadone⁹, which is a substrate for the rat and rabbit hepatic microsomal N-demethylase enzymes¹⁰. We therefore examined the activity of N-demethylase in the livers of mice maintained on the same regimen as that described above. The activity of N-demethylase was assayed in the hepatic 12,000g supernatant fraction¹¹ 6 d after removal of the morphine pellet. Ten micromoles of D,L-methadone were used as substrate. The 6-d oral administration of methadone brought about a nearly twofold increase in the activity of the enzyme. This increase in enzyme activity may account for the elevation of the methadone LD₅₀ which was determined in identically treated animals. Since N-demethylation plays only a minor role in the inactivation of morphine⁷, the fact that the LD₅₀ for morphine was unchanged is not surprising.

To demonstrate that the elevation in the methadone LD₅₀ was the result of increased N-demethylase activity following methadone administration and not residual cellular tolerance brought about by the morphine pellet treatment, we gave naive mice phenobarbital intraperitoneally (50 mg kg⁻¹ d⁻¹), which increases the activity of a variety of microsomal enzymes¹². After 3 d of treatment, a nearly sixfold increase in N-demethylase activity occurred (Table 2). There was a concomitant fourfold increase in the oral LD₅₀ for methadone. A less dramatic but significant increase of 55% in the intraperitoneal methadone LD₅₀ was also noted. In contrast, the intraperitoneal morphine LD₅₀ was not significantly affected by the barbiturate treatment. Since these mice had never been exposed to narcotics, it seems that a change in disposition of methadone did occur.

The increased activity of N-demethylase observed as a result of methadone treatment is not a consequence of the morphine pellet treatment since morphine treatment has been shown to lower N-demethylase activity significantly². To demonstrate the ability of methadone to increase N-demethylase activity, naive mice were given oral doses of methadone (50 mg kg⁻¹) daily. After 24 h, a 50% increase in the activity of N-demethylase was noted. By day 6, the activity was increased nearly twofold (compare 0.770 ± 0.124 with 1.419 ± 0.124 μmol of formaldehyde per 30 min per liver).

Table 3 demonstrates the similarities between the effects of methadone and phenobarbital on liver protein content and liver weights. Both treatments caused a significant elevation in the liver weights and in the protein of the 12,000g supernatant fraction and of the microsomal fraction of the liver.

Table 1 Effects of repeated methadone treatment on methadone and morphine lethality and activity of liver N-demethylase in mice rendered tolerant by implantation of a morphine pellet

Treatment	Methadone LD ₅₀ ± s.e. (mg kg ⁻¹ , p.o.)	Morphine LD ₅₀ ± s.e. (mg kg ⁻¹ , i.p.)	N-demethylase activity (μmol formaldehyde/ 30 min/liver ± s.e.)
Water	120 ± 4 (24)	404 ± 27 (24)	0.770 ± 0.124 (11)
Methadone	198 ± 21* (24)	407 ± 34 (24)	1.42 ± 0.12* (11)

Mice were implanted with 75 mg morphine base pellets for 3 d (ref 8). Treated animals were given 100 mg kg⁻¹ of D, L-methadone HCl in water (5 mg ml⁻¹) orally once a day for 6 d after removal of the pellet. Controls were given equivalent volume of water. All determinations were made approximately 5 mg of microsomal protein per assay from the 12,000g supernatant fraction of mouse livers. The assay procedure of Fouts¹¹, using 10 μmol (2 mM) of D, L-methadone HCl as substrate, was used. Numbers in parentheses indicate number of animals in each group.

* Significantly different from controls, *P* < 0.05.

i.p., Intraperitoneally; p.o., orally.

Table 2 Effect of phenobarbital treatment on methadone and morphine lethality and activity of liver N-demethylase in naive mice

Treatment	Methadone LD ₅₀ ± s.e. (mg kg ⁻¹)	Morphine LD ₅₀ ± s.e. (mg kg ⁻¹)	N-demethylase activity (μmol formaldehyde/30 min/liver ± s.e.)
Saline	84.0 ± 4.6 (24), p.o. 40.0 ± 2.8 (24), i.p.	480 ± 44 (24)	0.598 ± 0.026 (5)
Phenobarbital	304 ± 42* (24), p.o. 62.0 ± 2.6* (24), i.p.	547 ± 23 (24)	3.58 ± 0.23* (5)

Mice were injected intraperitoneally with 50 mg kg⁻¹ phenobarbital in saline (5 mg ml⁻¹) once a day for 3 d. Controls were injected with saline. All determinations were made 24 h after the last injection using the same procedures as in Table 1. Numbers in parentheses indicate number of animals in each group.

* Significantly different from controls, $P < 0.05$.

The increases in microsomal protein and N-demethylase activity after methadone seem to be typical of the phenobarbital type of induction of microsomal enzymes¹².

The principal metabolites of methadone are 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (M₁) and 2-ethyl-5-methyl-3,3-diphenyl-1-pyrroline (M₂)^{13,14}. Both are formed by N-demethylation of methadone and non-enzymatic cyclisation and, in the case of M₂, further N-demethylation¹⁵. These metabolites have been isolated from rat bile^{14,16} and urine¹⁶, as well as from human plasma^{17,18}, bile^{14,17} and urine^{13-15, 17,19}. They have no demonstrated analgesic activity¹⁴ and, therefore, probably play no role in the prevention of the narcotic abstinence syndrome. Thus, the increase in the activity of N-demethylase following repeated administration of methadone should increase the rate of

drug (50 mg kg⁻¹). Subcutaneous administration of methadone brought about a much smaller decrease in this half-life.

These observations may have clinical implications for methadone maintenance in which doses are often greater than one-half the minimal lethal dose in non-tolerant subjects. Rapid inhibition of microsomal metabolism can follow after exposure to a number of drugs and environmental agents^{26,27}. Morphine and heroin, for example, are abused by subjects on methadone maintenance and are effective microsomal enzyme depletors^{2,28}. Furthermore, the occurrence of microsomal enzyme inhibition is compounded when methadone is taken orally, a route which is associated with a slow onset and prolonged duration of drug action. Thus, toxic sequelae may not develop until the subject has

Table 3 Effects of phenobarbital and methadone on liver weights and protein in liver fractions

Treatment	Liver weight ± s.e. (g)	Protein in 12,000g supernatant fraction of liver ± s.e. (mg)	Protein in microsomal fraction of liver ± s.e. (mg)
Naive mice			
Saline (5)	1.42 ± 0.06	159 ± 7	62.6 ± 2.8
Phenobarbital (5)	1.68 ± 0.08*	203 ± 11*	85.9 ± 4.3*
Mice implanted with morphine pellet			
Water (10)	1.37 ± 0.06	109 ± 8	50.4 ± 3.6
Methadone (14)	1.69 ± 0.06*	127 ± 6*	60.4 ± 2.7*

Naive mice were injected with phenobarbital or saline according to the procedure in Table 2. Mice implanted with 75 mg morphine base pellets were given either D,L-methadone HCl or water orally for 6 d according to the procedure in Table 1. All determinations were made 24 h after the last dose. The microsomal fraction was obtained by centrifuging 1-ml aliquots of the 12,000g supernatant fraction at 105,000g for 1 h. Proteins were determined by the method of Lowry *et al.*³⁰. No significant differences were noted in the body weight data. Numbers in parentheses indicate number of animals in each group.

* Significantly different from controls, $P < 0.05$.

inactivation of the narcotic and contribute to the development of tolerance to some methadone effects.

There is circumstantial evidence for the role of metabolism in the termination of the pharmacological actions of methadone. Basic metabolites of methadone are significantly elevated in the faeces of rats after repeated methadone administration²⁰. These compounds are probably M₁ and M₂ since both have a higher pK_a than methadone²¹ and represent the greatest portion of methadone metabolites^{14,15}. More recently, pretreatment with methadone for 15 d was shown to increase the biliary excretion of M₁ by 50% and advance its peak excretion time¹⁶. Since biliary excretion accounts for the majority of these compounds in the faeces²², these two observations support the possibility that increased activity of microsomal enzymes is the consequence of the repeated administration of methadone.

Alvares and Kappas²³ showed that phenobarbital pretreatment of rats results in an enhancement of demethylation of methadone *in vitro* by liver microsomal preparations and that the analgesic effect of methadone decreases concomitantly. No increased N-demethylase activity was demonstrated following chronic administration of methadone (20 mg kg⁻¹, intraperitoneally), however. Peters²⁴ was also unable to demonstrate enhanced demethylation after daily intraperitoneal injections of methadone (5 mg kg⁻¹) in rats. In contrast, Misra *et al.*²⁵, using an oral rather than a parenteral route, observed that the biological half-life of methadone in the plasma and brain of rats was reduced more than fourfold after repeated administration of the

left the methadone maintenance centre for the day.

Increased neonatal mortality in offspring of male rats treated with methadone or morphine before mating

METHADONE ((\pm)-4, 4-diphenyl-6-dimethylamino-3-heptanone hydrochloride) is a potent (addictive) analgesic with pharmacological effects which are qualitatively similar to those of morphine, although it is far more effective than morphine when given orally. Its ability to diminish the severity of the abstinence syndrome resulting from heroin withdrawal led to the introduction of methadone in the chemotherapy of narcotic addiction¹⁻³. Little is known, however, about its long term toxicity effects. We report that treatment of male rats with either (\pm)-methadone HCl (METH) or morphine sulphate (MS), given orally, for 24 h before mating to untreated females increases the neonatal (21-d) mortality of their offspring.

Sixty naive female Charles River (CD) albino rats (which had not been previously treated with the drug) were mated to 26 male rats which had received 13, 18 or 38 mg kg⁻¹ d⁻¹ METH during

Fig. 1 Neonatal (21-d) survival of 166 live offspring sired by male rats pretreated with MS (○) and 145 live offspring sired by male rats pretreated with METH (●). Twenty-six per cent of the offspring sired by METH pretreated males and 66% of the offspring sired by the MS pretreated males survived. Of the live offspring of untreated males 90-95% survived for 21 d.

the previous 24 h. Another 60 naive female rats were mated to 26 other male rats similarly treated with 22, 47 or 55 mg kg⁻¹ d⁻¹ MS. Females were exposed to treated males for 7 consecutive days.

Figure 1 shows the marked difference in the 21-day mortality of the offspring. Those from MS-treated males (six fostered and ten unfostered litters) had 57 deaths out of 166 live births (34% mortality), whereas those from METH-treated males (seven fostered and seven unfostered litters) had 107 deaths out of 145 live births (74% mortality). This difference is very significant ($\chi^2 = 46.77$, $P < 0.001$). The METH offspring ($n = 145$) died at the rate of 8 per day from days 4 to 14, whereas the MS offspring ($n = 166$) died at a rate as high as 6 per day only between days 11 and 14, suggesting that a different lethal mechanism is operating. Overall mortality in both groups is considerably greater than the 5.9% rate in 1,645 offspring resulting from matings of untreated males and females, and reared by untreated foster mothers^{4,5}.

We also investigated the effects of pretreating male rats for 24 h with METH given 0-24 h or 25-48 h before mating with naive females ($n = 12$ in each group). Males were first placed in a cage and provided with a 5% sucrose drinking water

Fig. 2 The 21-d survival of the offspring of naive females mated with male rats pretreated with either no drug (▲) or with low-dose METH (○, 25 mg kg⁻¹ d⁻¹) or high-dose METH (●, 52 mg kg⁻¹ d⁻¹) during the 24-h period before mating. These three mortality rates differ significantly ($P < 0.01$) from each other.

solution containing 0.67 mg ml⁻¹ or 0.067 mg ml⁻¹ METH. The 'high-dose' METH males received 52 mg kg⁻¹ d⁻¹, the 'low-dose' METH males 25 mg kg⁻¹ d⁻¹. A third group received sucrose solution alone. Each male remained in this cage with four females for 24 h. (The offspring of these females are not part of the present study.) Males were then moved to a second cage provided with drinking water with neither drug nor sucrose, containing four drug-naive females, the offspring of which are identified as the '0-24 h' offspring, as the males had received METH in that period prior to siring these offspring. After 24 h with these females each male was then moved to a third cage provided with pure drinking water and containing

four more naive females, the offspring of which are identified as the '25-48 h' offspring. After 24 h with these females each male was then returned to the initial cage containing the drinking water with 5% sucrose solution (with or without METH) and the cycle repeated. Each naive female was exposed to males for 6 consecutive days.

The neonatal (21-day) mortality of the offspring of the three groups of males is shown in Fig 2. In 21 days, 13% of 132 offspring sired by control males died, whereas 56% of 100 offspring sired by high-dose METH males died (difference very significant $\chi^2 = 47.08$, $P < 0.001$) and 34% of 100 progeny of low-dose METH males died (difference from controls significant $\chi^2 = 13.59$, $P < 0.01$, and from high-dose of METH progeny $\chi^2 = 8.91$, $P < 0.01$). The neonatal mortality of 244 offspring of males which had received METH 25-48 h before mating was only 25%. This did not differ significantly ($\chi^2 = 3.41$, $P > 0.05$) from the 21-day mortality of their controls (17%). Of the ten litters sired by control males only one had a death rate in excess of 30% (Fig 3), whereas of the eight litters sired by the high-dose METH males, six litters lost 40% or more of the offspring born alive. The low-dose methadone litters had a smaller death rate than the high-dose METH offspring. These data demonstrate that the increased mortality of the METH-sired offspring is not simply a consequence of the deaths of the offspring of a small proportion of the males, but of an increased mortality in virtually all litters.

Pretreatment of male rats with METH before mating thus produces a significant increase in neonatal (21-day) mortality of the offspring of the METH-treated males and naive females when compared to control matings. Our data show a dose-response relationship for this phenomenon as well as evidence

Fig 3 Survival and death in each litter of offspring born to females mated to (a) controls and males receiving (b) low- and (c) high-dose METH 0-24 h before mating. The vertical black bars show the survival or death of the live offspring from each litter. \circ , Females which did not deliver offspring.

that the lethal effect is seen primarily in offspring sired during the first 24 h following administration of METH to the male. Morphine produced a similar but less marked effect. An urgent problem in medicine is the fact that 1-3% of all infants born have one or more unexpected congenital anomalies which cannot be explained by classical teratology. Our preliminary results suggest that it is necessary to investigate not only the drugs which were administered to the mother before and during pregnancy, but also those drugs used by the father. This approach may contain the answers to some of the unexplained problems of childhood growth and development.

We thank Norman F. Sourdiff for technical assistance and Sue Mauldin Smith for statistical computations.

Physiology of visual cells in mouse superior colliculus and correlation with somatosensory and auditory input

THE two main targets of the mammalian optic nerve fibres are the lateral geniculate body and the superior colliculus (optic tectum). From studies with various techniques, and in several mammalian species including the cat¹⁻⁵, monkey⁶⁻⁸, rabbit¹⁰⁻¹², rat¹³, and ground squirrel¹⁴ three major functions of the superior colliculus have been described. In the superficial layers the visual input is processed in a specific way; in deep layers several sense modalities, chiefly visual, auditory and somatosensory, are brought together, stimulation of the tectum results in an orienting of the animal's eyes, head or body towards a location corresponding topographically to the part of the tectum stimulated.

Gordon¹ has shown that for a given location in the cat tectum there is a good correlation between the positions of visual receptive fields and the directions from which maximal auditory responses are evoked. She also found a correlation between preferred directions of stimulus movement in the two modalities. The agreement between visual and somatosensory cells was much looser, although visual receptive fields near the vertical midline were correlated with tactile fields on the face, and temporal visual fields, with tactile fields on the body or legs. She rarely observed responses from whiskers. Cats move their eyes and especially their heads extensively, however, and a very close relationship between retinotopic and somatosensory maps was perhaps not to be expected.

We have studied the superior colliculus in the mouse, a small compact animal with very little eye movement and relatively little head movement, a mouse rather turns its whole body towards an interesting object. The major part of the mouse's visual field is crossed by an elaborately developed somatosensory organ, the vibrissae. Whisker movement in the mouse is very rapid, but the excursions are small, so that the whiskers bear a relatively constant relationship to the visual field. One should therefore not be surprised to find a close topographical relationship between the tectal projections from retina and whiskers.

In our study, ten mice of the C57BL/6J strain were used. Throughout the experiment a mouse was kept under light anaesthesia (pentobarbital and chlorprothixene) and was neither paralysed nor artificially respirated (For exact procedures, see Dräger¹⁵). The head was held fixed by means of a small metal block glued to the skull, thus leaving the ears free. Visual receptive fields were mapped on a translucent tangent screen placed at a distance of 10.5 cm from the mouse. Electrolytically polished tungsten electrodes were used for recording. Electrode tracks, most of which were perpendicular to the tectal surface, were marked by several small electrolytic lesions (2 μ A for 2 s) and reconstructed histologically. A total of 323 recordings were made in 48 penetrations. Of these records, 145 were probably from tectal cells. The remaining 178 recordings, from unit clusters or poorly resolved units, were useful for purposes such as topographical mapping of the tectal surface.

Cells in the superficial layers had small visual receptive fields (average diameter 9°) whose locations in the visual field varied according to a topographical map similar to that described for other vertebrates¹⁶: the nasal visual field projected anteriorly and the upper visual field medially. These cells responded only to visual stimulation, with best responses to a slowly moving small spot of any shape. One-quarter of the cells preferred one direction of movement, for most cells, the preferred direction was upward. Deeper in the tectum most visual cells had very different receptive-field properties, with large fields (20°-60°), sluggish and transient responses to small moving objects, little or no response to large stimuli, and often a directional selectivity with preference for upward movement. Characteristically these deeper-layer cells tended

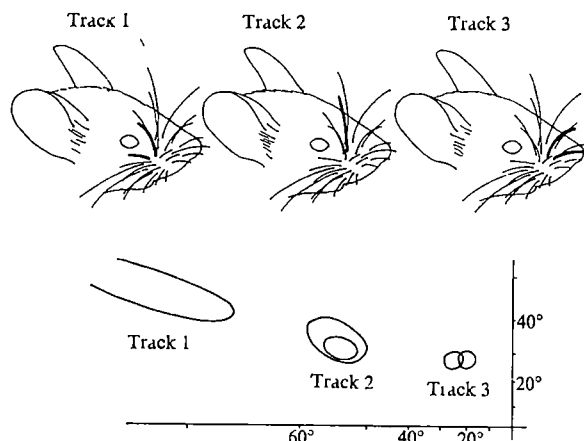

Fig. 1 Correlation between somatosensory and visual receptive fields recorded in three successive electrode penetrations. Lower part of diagram shows visual receptive fields recorded in superficial tectal layers and mapped on tangent screen. Mouse was facing the tangent screen at right angles, 10.5 cm behind it. Origin of coordinate axes marks intersection with the long axis of the mouse. Upper part of the diagram indicates whiskers giving strongest responses in the same electrode tracks at a deeper level, these whiskers are drawn as thicker lines.

to habituate if the same stimulus was repeated, but fired again if the spot or object was moved through a different part of the field. Similar visual receptive field properties in the superior colliculus have been described in other species^{5,6,10,12,13}.

At a slightly deeper level, in the stratum griseum mediale, cells responding to somatosensory or auditory stimulation were first encountered intermixed with visual cells, and with cells responding to two (or rarely to all three) modalities. Still deeper in the tectum, over a distance of several hundred μm , somatosensory or auditory modalities tended to take over completely until, in some penetrations, the electrode again entered an area of mixed responses. There was no segregation of somatosensory and auditory cells into sub-layers, cells responding to a given modality seemed rather to be arranged in clusters with some intermixing at the boundaries between clusters.

Somatosensory responses were obtained about twice as frequently as auditory. In most penetrations the tactile receptive fields were located on one or a few whiskers. Gently tapping one whisker evoked a short burst of spikes with little difference in response as the direction of hair deflection was varied.

The most striking feature was a very consistent relationship in any one electrode track between the location of visual receptive fields and that of somatosensory receptive fields. A series of three electrode tracks in one experiment is illustrated in Fig. 1. The axes in this illustration represent the horizon and the vertical midline of the mouse, drawn on the tangent screen so as to cross at the extended longitudinal axis of the mouse. Numbers on the axes mark degrees of eccentricity. Visual receptive fields in the three tracks are outlined on the screen. In the upper part of the figure, the whiskers giving the strongest responses from cells deeper in the tectum are drawn more heavily than the others. In the first track there was a clear correlation between temporal visual fields and posterior whiskers, moving nasally in the visual field in tracks 2 and 3 was accompanied by movement to more anterior whiskers. In other series of penetrations a similar correlation was seen between visual receptive-field positions and the whiskers that evoked the best responses at deeper levels in the tectum. If the visual receptive fields were progressively lower in a set of tracks, the whisker fields likewise moved down. By drawing the projections of the whiskers through the eye on to the tangent screen, we could show that for a given perpendicular penetration the visual receptive fields were crossed by just the whiskers that evoked maximal responses from the somatosensory cells

deeper in the tectum. This correlation held not only for neighbouring visual and somatosensory cells, but also for single cells driven by both modalities.

In parts of the tectum in which visual receptive fields were far peripheral, and no whiskers lay in the way, somatosensory responses at deep levels were evoked from other parts of the body. Visual fields far down, where the mouse might see its own paw, were associated with tactile fields on the dorsum of the paw. Far temporal visual fields were correlated with somatosensory fields on the flank, shoulder and ear, here an upward movement in the visual field was paralleled by upward movement in the somatosensory map, from the flank to the tip of the ear.

Reactions to auditory stimulation were found less frequently than to tactile stimuli and they tended to be less well localised. Auditory responses could be evoked by complex sounds rich in high frequencies like clicks or crackling noises. Usually only sounds generated from a direction contralateral to the colliculus were effective in driving auditory cells. In eight out of thirteen cells the auditory receptive field in the horizontal plane was restricted to an angle of about 50° – 150° , which included the visual and somatosensory receptive field of cells recorded simultaneously or in the close vicinity.

The mouse superior colliculus thus contains three topographical maps, superimposed and roughly in register, of the surroundings as observed through visual, somatosensory and auditory modalities. We assume that this system serves to orient the animal to an interesting stimulus whatever the sense modality.

We thank David Freeman for designing the electronic equipment and Claire Wang for histological assistance. The work was supported by a grant from the National Institutes of Health and by grants from the Rowland Foundation, Inc., and the Esther A. and Joseph Klingenstein Fund, Inc.

Conductance of channels opened by acetylcholine-like drugs in muscle end-plate

MOST recent views of the way in which acetylcholine (ACh) can cause ion channels to open postulate that the channel can exist only in one or other of two distinct conformations, open or shut^{1–4}. In their simplest form, these theories predict that a channel, once it is open, will have the same conductance whichever drug caused it to open. We have estimated average single channel conductances for four cholinomimetic agonists, and find this prediction is not confirmed.

The mean single-channel conductance, and mean lifetime of the open state, have been estimated at the voltage-clamped end-plate of the frog (summer *Rana pipiens*) cutaneous pectoris muscle. Methods similar to those of Anderson and Stevens⁵, were used with the addition of Normarski interference optics,

which make the end-plate clearly visible. The drugs shown in Fig 1 were applied iontophoretically to the end-plate, and samples of the end-plate current fluctuations taken at $1,024 \text{ s}^{-1}$. The mean single-channel conductance, γ , was estimated from the total variance, s_I^2 , of the current fluctuations, as $\gamma = s_I^2/m_I(V - V_{eq})$, where m_I = mean end-plate current induced by the drug, V = membrane potential and V_{eq} = equilibrium potential. This method assumes that the fluctuations represent the random opening and closing of channels, and that no appreciable contribution to s_I^2 occurs outside the frequency range examined in our experiments (1–500 Hz).

Measurements in both normal and in glycerol-pretreated muscle fibres showed that V_{eq} was the same (near 0 mV), within a few mV, for all the drugs in Fig 1. Measurements on normal fibres were obtained by depolarising in small steps of a few mV, spaced by about 10 s, as the contraction threshold (about –55 mV) was approached, until about –30 mV was reached at which point the excitation-contraction mechanism was inactivated. The variance was estimated from the variance of the digitised noise record, and as

$$s_I^2 = \int_{-\infty}^{\infty} S(f) df = \int_0^{\infty} G(f) df$$

where $S(f)$ is the two-sided, and $G(f) = 2S(f)$ the one-sided spectral density computed from the fluctuations. These methods gave very similar results.

The results are shown in Table 1. The means for all experiments are given, because the results were reproducible from day to day. For example, three separate experiments with suberyllcholine (SubCh) gave $\gamma = 28.4 \pm 1.6$, 28.2 ± 2.2 , and $29.2 \pm 2.4 \text{ pmho}$.

It is clear from these results that the mean single-channel conductances, γ , are not the same for all drugs, but that they vary over an approximately twofold range for the drugs tested. In all seven experiments in which SubCh and ACh were tested on the same cell, it was found that SubCh had a larger γ than ACh, the mean ratio being 1.19 ± 0.04 . SubCh also had a longer mean open lifetime than ACh, by a factor of 1.7 (Table 1), the same as the factor found by Katz and Miledi⁷. The agonists 3-phenylpropyltrimethylammonium (PPTMA) and 3-(*m*-hydroxyphenyl)propyltrimethyl ammonium (HPTMA), which are full agonists as judged by their ability to cause contraction of the frog rectus abdominis muscle⁸, have a substantially smaller γ than either ACh or SubCh.

Katz and Miledi⁷ have already shown that the mean length of time for which the ion channel stays open may differ over an approximately tenfold range for different drugs, at the frog muscle end-plate. Contrary to the predictions of the simple two-state theories, it seems that differences in agonist action that can produce a tenfold difference in the mean time that a channel remains open, can also influence the mean conductance of the open channel. For the drugs tested at least, γ varies much less than the mean open-channel lifetime, τ , from drug to drug. It is also intriguing that a large single channel conductance seems to accompany a large open lifetime, but not enough drugs have been tested yet to allow any generalisation to be made.

Table 1 Values of mean single-channel conductance (γ) computed from integrated spectral densities for current fluctuations, and values of mean open-channel lifetime, τ , at 10–15°C and a membrane potential of between –60 and –80 mV, computed as $1/(2\pi f_c)$ where f_c = half-power frequency

	γ (pmho)	τ (ms)
SubCh	28.6 ± 1.0 (22)	5.6 ± 0.3 (8)
ACh	25.0 ± 0.9 (8)	3.2 ± 0.3 (6)
HPTMA	18.8 ± 0.8 (19)	1.0 ± 0.06 (13)
PPTMA	12.8 ± 1.1 (7)	0.83 ± 0.02 (3)

The frog Ringer solution contained tetrodotoxin (100 nM). All results are on normal (not glycerol-treated) fibres. The table gives the mean of values on all cells \pm s.e., with the number of determinations in parentheses.

Suberyllcholine (SubCh)

3-(*m*-hydroxyphenyl) propyltrimethyl ammonium (HPTMA)

3-phenylpropyltrimethyl ammonium (PPTMA)

Fig. 1 Drugs applied iontophoretically to *Rana* muscle end-plate

The spectra of current fluctuations produced by ACh and SubCh could be fitted well with a single time constant ' $1/f$ ' model^{1,5}. The mean single channel conductance, estimated from the zero frequency asymptote of spectral density⁶, as $\gamma = S(0)/2m_I(V - V_{eq})\tau$, agreed well with estimates of γ from the noise variance in the case of these drugs. The spectra of the other two agonists, however, had a component at low frequency, in addition to the major high frequency component. The sum of two single time-constant spectra was found to fit these results. The 'mean open lifetimes' in Table 1 were derived from the high frequency component, but whether or not they estimate accurately the lifetime of an actual species depends on the explanation for the two components that is adopted. It is possible that several species of channel exist with different mean open times, corresponding, conceivably, with the binding of different numbers of agonist molecules. But it can be shown quite simply that if the channels all have the same conductance when they are open, then the value of γ calculated from the noise variance should be this conductance, regardless of how the channels are distributed among the species of different mean open lifetimes⁶.

Two classes of explanation can be imagined for the observation that mean single channel conductances are not the same for all drugs. It could be that the channel can exist in several distinct open conformations, each of which has a different conductance, and that different drugs favour different conformations. On the other hand, it could be that the open channel has essentially the same conformation for all drugs, but individual drugs have, for example, somewhat different effects on local field strength or local pH so that each drug affects the pK of ionisable groups, or access of ions to the channel, in a slightly different way. It has been reported⁹ that reduction of the ACh receptor with dithiothreitol changes ACh voltage fluctuations in a way which suggests that the primary change is a lowered single-channel conductance.

Our conclusions depend, of course, on the correct estimation of γ . It is conceivable, for example, that current fluctuations actually reflect receptor occupancy by the drug⁵, and that the channel oscillates more rapidly than we can observe between open and shut states while it is occupied. In this case our estimates of γ would be only a lower limit of the true open channel conductance.

We thank Dr R. B. Barlow and Dr A. Ungar who gave us the drugs. This work was supported by the United States Public Health Service and the Wellcome Trust.

Reversible spectral change of squid retinochrome by salts

THE cephalopod retina contains two kinds of photosensitive pigments, rhodopsin and retinochrome. Retinochrome was first found in the inner segment of squid visual cells¹. More recently it was reported that the outer segment might also contain retinochrome together with rhodopsin². The chromophore of retinochrome, all-*trans* retinal, is predominantly converted into the 11-*cis* form by illumination. It has been suggested that retinochrome supplies 11-*cis* retinal for the regeneration of cephalopod rhodopsin in the dark, by acting as an isomerase¹. The validity of the mechanism, however has not yet been established *in vitro* or *in situ*.

The chemical behaviour of retinochrome has been studied and compared with that of rhodopsin^{1,3}. Retinochrome has an absorption spectrum that depends on pH, and is sensitive to hydroxylamine and NaBH₄, while rhodopsin has an absorption spectrum independent of pH and is not affected by those reagents. This suggests that the link between chromophore and protein in retinochrome is more susceptible to the environment than in rhodopsin. On the other hand, evidence from circular dichroism measurements indicates that the chromophore of retinochrome is fixed to the protein part so that its rotation is restricted as in rhodopsin^{2,3}. Here we show that the absorption maximum of retinochrome is shifted to the shorter wavelength with increasing salt concentration.

Eyes were enucleated from fresh squids (*Todarodes pacificus*) under dim white light, frozen immediately, and stored at -20° C until used. For each preparation, we used about 40 eyes. They were thawed gradually at room temperature and bisected, after which the hemispheres containing the retinae were shaken in phosphate buffer (1/15 M, pH 6.8) in order to detach the outer segments of the visual cells and free the retinae

Fig. 1 Absorption spectra of retinochrome at pH 5.4 and 13° C. Curve 1 is the absorption spectrum of desalted retinochrome—digitonin solution. Next, solid NaCl (60 mg) was added to the solution (1 ml) and the pH was adjusted to 5.4 by addition of 0.6 μl 1 N NaOH (curve 2). Curve 3 is the spectrum of the sample after desalting by dialysis.

Fig. 2 Absorption maxima of retinochrome (●), rhodopsin (○) and acid-metarhodopsin (□) in various concentrations of NaCl at pH 5.4. The salt concentration of the samples was increased by addition of solid NaCl. When the sample became turbid by addition of NaCl, the absorption maximum was determined after centrifugation for 1 h at 28,000g at 4° C. Acid-metarhodopsin was prepared by converting rhodopsin to alkaline metarhodopsin by exposure to yellow light ($\lambda > 520$ nm) at pH 10, and then lowering the pH to 5.4.

containing the retinochrome. From the outer segment we extracted rhodopsin according to a method described previously². When retinochrome had been extracted from the outer segments together with rhodopsin, the two were separated by the chromatographic method described previously². Retinochrome was prepared from the outer segment-free retinae¹.

Ommochrome was eliminated from the extracts by passing them through a DEAE cellulose column (1 cm in diameter and 5 cm in height). The extract was placed on top of a column equilibrated with 0.02 M phosphate buffer (pH 6.8) and eluted with 0.02 M phosphate buffer containing 0.1% digitonin. As ommochrome was strongly adsorbed at the top of the column, eluates were free from ommochrome. The eluates were gathered, concentrated by a Sartorius membrane filter and then desalted by passage through a Sephadex G-25 column (1 cm in diameter and 20 cm in height), which was equilibrated with non-ionic 0.1% aqueous digitonin. We used the desalted retinochrome and rhodopsin samples to investigate the effect of salt on retinochrome and rhodopsin. Absorption spectra were measured with a 124 type Hitachi spectrophotometer at 13° C. Ionic strength was monitored with a conductivity meter (CD-35 M II, MS K1K1).

Figure 1 shows the absorption spectrum of retinochrome from 340–600 nm at pH 5.4. Retinochrome has an absorption peak at 488 nm in desalted digitonin solution (curve 1). When solid sodium chloride was added to this sample to a final concentration of 1 M, the absorption maximum was shifted to 478 nm (curve 2). At this salt concentration, no further change of the absorption spectrum was observed for at least 8 h at 13° C. When the sample was desalted by dialysis with a Sartorius membrane filter against distilled water for 5 h at 5° C, it again exhibited an absorption spectrum with the peak at 488 nm (curve 3). The absorbance at 488 nm was reduced to about half the initial value, because of the dilution of the sample during dialysis. This result shows that the change in the λ_{max} of retinochrome by salt is reversible.

Figure 2 shows the effects of salt concentration on the λ_{max} of retinochrome, rhodopsin and acid-metarhodopsin at pH 5.4. The λ_{max} of retinochrome shifted considerably at concentrations between 0.1 M and 0.5 M NaCl, and was at 475 nm in 5 M NaCl, while no shift of λ_{max} of rhodopsin and acid-metarhodopsin was observed. We further investigated the effect of various salts (NaCl, KCl, LiCl, MgCl₂ and CaCl₂) on the λ_{max} of retinochrome. All the salts so far examined caused the shift of the λ_{max} from 488 nm to a limit of 475 nm at pH 5.4.

with increasing concentration. The concentration necessary for a 6-nm shift, about a half the maximum, was 0.03 M for CaCl_2 and MgCl_2 , 0.2 M for KCl and LiCl , and 0.4 M for NaCl .

Next, we examined the salt effect on the absorption spectrum of retinochrome in alkaline solution. When retinochrome was brought from pH 5.4 to pH 9.5 in desalted solutions, its λ_{max} shifted from 488 nm to 495 nm. At the same time, the absorbance at 495 nm became smaller than the initial absorbance at 488 nm and another peak appeared at 370 nm, as already reported^{1,2}. When solid sodium chloride was added to the alkaline solution to a final concentration of 1 M, no shift of either of the absorption peaks at 495 nm and 370 nm was observed. Figure 3 shows the effect of pH on λ_{max} of retinochrome in digitonin solutions containing 0.01 M and 1 M NaCl . The λ_{max} of retinochrome gradually changed from 484 nm at pH 4.5 to 495 nm at pH 9.3 in 0.01 M solution. In 1 M NaCl the λ_{max} was 476 nm at pH 4–5 and shifted to longer wavelengths above pH 6, reaching a limit of 495 nm at pH 9.3. This result indicates that the salt affects the pH dependency of the absorption peak of retinochrome.

It has been suggested that the λ_{max} of rhodopsin could be explained on the basis of a protonated Schiff base of retinal and amino group of opsin, for the λ_{max} of a protonated Schiff base tends to shift to the longer wavelengths, when the protonated portion $-\text{C}=\text{N}-$, is at a longer distance from a

negative counter anion, so that the net charge on the protonated Schiff base is more positive^{4,5}. We believe that the absorption peak of retinochrome is also due to a protonated Schiff base of retinal with the protein like that of rhodopsin. The following mechanism can therefore be considered for the dependence of λ_{max} of retinochrome on salt concentration. First, there is a direct action of the salt on the primary binding site, Schiff base linkage. Anions such as chloride will concentrate at the protonated portion of the Schiff base linkage and decrease its net positive charge. Although the chromophore binding site in retinochrome is probably more exposed than in rhodopsin, the shift in λ_{max} of retinochrome is not adequately explained by such a direct action of anions, because it depends on the species of cation, as described.

A second explanation involves the indirect actions of salts on retinochrome. It is well known that salts such as LiCl and CaCl_2 at concentrations above 1 M cause the denaturation of some proteins⁶. Furthermore, in the bleaching of cattle rhodopsin, an increase in ionic strength facilitates the conformational change in the protein moiety that corresponds to the conversion from Meta I to Meta II⁷. Salt may affect some of the dissociated amino acids residues in the protein parts resulting in conforma-

tional change in protein parts. Such a mechanism is also probable in the case of retinochrome. If the increase in salt concentration causes conformation changes of the protein moiety and thereby decreases the distance between the protonated Schiff base and its counter anions this could result in the blue shift of λ_{max} of retinochrome to shorter wavelengths. On the other hand, λ_{max} of cephalopod rhodopsin, metarhodopsin and other visual pigments are not affected by salt concentration. This suggests that the chromophore binding site in retinochrome is not so deeply embedded in the protein moiety as are those of the visual pigments and/or that the protein moiety surrounding the binding site is very different in retinochrome and in the visual pigments.

Further investigations on the binding site of the chromophore of retinochrome in comparison with that of rhodopsin and metarhodopsin may help to clarify the interrelationships between retinochrome and rhodopsin.

Non-constant evolution rates in amino acid sequences of guinea pig, chinchilla and coypu pancreatic ribonucleases

THE primary structures of the pancreatic ribonucleases from cow¹, rat², pig³, horse⁴, red deer and roe deer⁵, sheep⁶, goat⁶ and giraffe⁶ have been determined. From an analysis of these data we concluded that mammalian pancreatic ribonucleases have evolved with a rather constant evolution rate of about 1% substitution every 3 Myr (ref. 6). The validity of this conclusion, however, and possible exceptions have to be tested on a larger number of primary structures of mammalian ribonucleases.

As the amino acid sequences of the insulins from guinea pig and coypu differ markedly from those of other mammalian species^{10,11}, the amino acid sequences of other proteins from hystricomorph rodent species are of great interest. Here we describe the amino acid sequences of the pancreatic ribonucleases from the hystricomorph rodent species guinea pig (*Cavia porcellus*), chinchilla (*Chinchilla brevicaudata*) and coypu (*Myocastor coypus*). Bartos and Uziel¹² described the isolation of two ribonuclease components from guinea pig pancreas. We have reproduced this finding and demonstrated that both components differ in amino acid sequence.

Ribonucleases were isolated by extraction of pancreatic

Fig. 3 Dependence of λ_{max} of retinochrome on pH in digitonin solutions containing 0.01 M (○) and 1 M (●) NaCl . When the samples became turbid by the acidification or alkalisation, they were centrifuged 1 h at 28,000g at 4°C before measuring their absorption spectra.

tissue with 0.125 M sulphuric acid, precipitation with acetone, ammonium sulphate fractionation, gel filtration on Sephadex G-25 and repeated chromatography on CM-cellulose (according to Åqvist and Anfinsen¹³ and with a sodium acetate gradient⁵, respectively). The amino acid sequences have been determined on tryptic digests of the aminoethylated proteins. The tryptic peptides have been positioned in the sequence by homology with other pancreatic ribonucleases and with each other. Full details of the isolation of the enzymes, several properties and the sequence determinations will be described elsewhere.

The coypu pancreas has one carbohydrate-containing ribonuclease component. From guinea pig pancreas two ribonucleases have been obtained, which not only differ in the presence (RNase B) or absence of carbohydrate (RNase A), but also in amino acid sequence. From chinchilla pancreas two carbohydrate-containing ribonuclease components have been obtained—one homogeneous and the other heterogeneous. The latter differs from the first in being more acidic and exhibits heterogeneity both in its carbohydrate moiety (glycopeptides both with and without sialic acid have been isolated) and in amino acid sequence.

Table 1 Difference matrix of pancreatic ribonucleases

	Cow	Pig	Horse	Coypu	Chinchilla	Guinea pig A	Guinea pig B	Rat
Cow	—	20%	27%	27%	24%	25%	27%	34%
Pig	26	—	23%	25%	22%	27%	21%	35%
Horse	35	30	—	25%	21%	26%	28%	34%
Coypu	36	33	33	—	15%	24%	20%	40%
Chinchilla	32	29	28	19	—	21%	22%	36%
Guinea pig A	33	36	34	31	27	—	24%	39%
Guinea pig B	35	28	37	26½	28½	31	—	40%
Rat	44	46	45	52	47	51	52	—

Both the number and percentage differences are calculated from a hypothetical maximum chain length of 131 residues.

(probably glycine at position 32 has been partially substituted by aspartic acid).

The amino acid sequences of coypu, chinchilla and guinea pig ribonucleases A and B are shown in Fig. 1. Chinchilla and guinea pig ribonuclease A have a 'normal' chain length of 124 residues. Coypu and guinea pig ribonuclease B have additional amino acid residues at the C-terminus as has been found earlier in horse ribonuclease⁵.

The origin of both guinea pig ribonucleases must reside

Fig 2 Amino acid residues in the ribonucleases of coypu, chinchilla, guinea pig (A and B) and the hypothetical ancestors of chinchilla and coypu ribonuclease, of the two guinea pig ribonucleases and of the hystricomorph rodent ribonucleases, at the 15 positions where three or four different residues are found in the four ribonucleases occurring now. The ancestral residues have been derived from the sequence data in Fig 1 and refs 1-9, and from the genetic code. Identical residues in coypu and chinchilla ribonuclease and in the two guinea pig ribonucleases are enclosed in blocks.

in a gene duplication. The many differences in amino acid sequence and also in other features make it unlikely that the two components represent alleles. The gene duplication may have occurred sometime before or after the divergence of the guinea pig from the other two hystricomorph rodent species investigated. In the first case we must assume that one of the two genes is a silent gene and does not come to expression in the other species or was lost again. In the other case the presence of two ribonuclease genes has been a novel acquisition in the line leading to the guinea pig, giving rise to new structural and functional possibilities which differ for the two gene products, resulting in an increased rate of acceptance of mutations. Here we provide evidence that the second possibility is more probable.

Table 1 is a difference matrix for the amino acid sequences of the ribonucleases from the hystricomorph rodents, cow, pig, horse and rat. Ribonucleases of species from different mammalian orders differ in about 30-35 positions (about 25%), with the exception of rat ribonuclease which differs in about 45-50 positions (about 35%) from all the others, including the hystricomorph rodent ribonucleases. Preliminary sequence information from the ribonuclease of the muskrat (a myomorph rodent species like the rat) indicates that the evolution rate of rat pancreatic ribonuclease has increased considerably after divergence of the cricetidae (including the muskrat) from the muridae (including the rat) (H van Dijk, A van den B, W Gaastra and J J B, unpublished).

The data in Table 1 show that the four hystricomorph rodent ribonucleases form a group of related sequences. But as a group they do not show the deviating behaviour from the homologous proteins of other mammalian species as has been encountered before with the insulins of the same species^{10,11}.

It is difficult to reconstruct the evolutionary history of amino acid sequences from a difference matrix if the evolution rates have not been constant and equal in all lines¹⁴. Therefore, we prefer to use an approximation of the ancestral sequence method^{15,16} for this purpose.

Excluding the additional residues at the C-terminus in coypu and guinea pig B, the 124 amino acid positions can be divided into three groups: (1) 85 out of 124 (69%) positions are identical in the four sequences (these are the blocked sequences in Fig 1) and are also, an indication of the relatively close relationship between them (Table 1); (2) 24 positions differ in only one of the four sequences, the other three are identical in these positions. The distribution of these 24 deviating residues between the four

sequences is as follows (Fig 1): three in coypu ribonuclease, four in chinchilla ribonuclease, ten in guinea pig ribonuclease A, seven in guinea pig ribonuclease B. These data point to an increased evolution rate in the two guinea pig ribonucleases as compared to the other two, but cannot provide us with the information necessary to deduce the evolutionary tree of the four sequences. (3) This goal must be accomplished with the data for the remaining 15 positions occupied by three or four different residues in the four sequences. The residues at these 15 positions are given separately in Fig 2. There are strikingly close relationships between the ribonucleases from chinchilla and coypu (seven identities) and the two guinea pig ribonucleases (five identities). Chinchilla and guinea pig ribonuclease A correspond in two positions, other combinations correspond in a smaller number of positions.

These data are the basis of the evolutionary history of the four hystricomorph rodent ribonucleases shown in

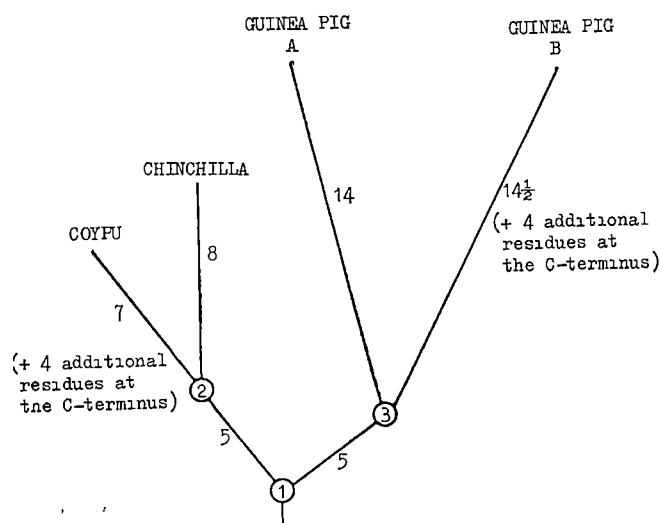

Fig 3 Evolutionary tree of the hystricomorph rodent ribonucleases. Node 1, hypothetical ancestor of the hystricomorph rodent ribonucleases; node 2, hypothetical ancestor of the ribonucleases of coypu and chinchilla; node 3, hypothetical ancestor of ribonuclease A and B of guinea pig. The number of amino acid substitutions between two sequences are given next to the lines connecting those sequences. The lengths of these lines are drawn in proportion to these numbers. It has been assumed for simplicity that the 24 positions which differ in only one of the four sequences (group 3 see text) are occupied in the three ancestral sequences by the residues which occur in three of the four sequences.

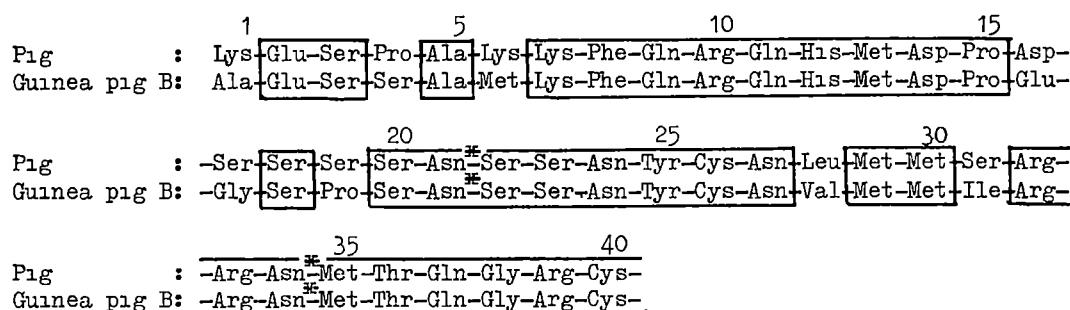

Fig. 4 Comparison of the N-terminal sequences of porcine and guinea pig ribonuclease B. Compare the similarities between these two sequences with the homologies in this part of the molecule of the hystricomorph rodent ribonucleases (Fig. 1) and between porcine and bovine ribonuclease³ Asn*, asparagine with carbohydrate

Fig. 3 Coypu and chinchilla ribonuclease have evolved with a rather normal evolution rate. The ancestral guinea pig ribonuclease has branched off considerably earlier than the divergence between coypu and chinchilla ribonuclease. The next event which took place was a gene duplication resulting in two guinea pig ribonucleases, which have diverged from each other with a considerably increased evolution rate.

The amino acid sequence of the carbohydrate attachment site Asn-21 is identical in porcine and guinea pig ribonuclease B. It is evident from the difference matrix (Table 1) that there are more similarities in structure between these two proteins (both sequences differ at 24 positions, excluding the four additional residues at the C-terminus in guinea pig B), so they differ significantly less than other ribonucleases from different mammalian orders. These structural similarities are predominantly found in the N-terminal part of the sequence (Fig. 4), where, as well as many identities, two strikingly conservative substitutions are also found at position 16 (Glu/Asp) and 28 (Val/Leu). Perhaps the formation of identical carbohydrate attachment sites at Asn-21 has necessitated the development of more structural similarities than the Asn-Ser-Ser (21-23) sequence. A point in case may be the formation of a hydrophobic surface on the protein near the attachment site of the carbohydrate. Two remarkable substitutions in guinea pig B are the valine at position 28 and the isoleucine at position 31 instead of the charged residues glutamic acid and lysine, respectively, which occur at these positions in the ribonuclease of the other hystricomorph rodents. These two residues are at neighbouring sites at the surface of the molecule (as can be deduced from a model of bovine ribonuclease S) and it is very likely that they are in contact with the carbohydrate chain attached to Asn-21. In porcine ribonuclease the positions 28 and 31 are occupied by the non-charged residues leucine (hydrophobic like Val-28 in guinea pig B) and serine, respectively. Thus, the structural similarity between porcine and guinea pig ribonuclease B may be a case of structural convergence of two homologous proteins which have developed identical secondary characteristics.

We thank Mrs E J van den Hende-Timmer for technical assistance. We also thank the Streeklaboratorium voor de Volksgezondheid, Groningen, for collecting pancreatic tissue from guinea pigs and Bosch Internationale Chinchilla, Aalst, The Netherlands for collecting pancreatic tissue from chinchillas. Part of this work was carried out under the auspices of the Netherlands Foundation for Chemical Research and with financial aid from the Netherlands Organisation for the Advancement of Pure Research.

A *cis*-dominant regulatory mutation affecting enzyme induction in the eukaryote *Aspergillus nidulans*

STUDIES ON *cis*-acting regulatory mutants (for example, operator and promoter mutants) in bacteria have been of crucial importance in understanding gene regulation¹⁻⁴. Similar mutants in eukaryote systems have not been extensively studied although there have been two reports of probable operator constitutive mutants in yeast^{5,6}. An understanding of eukaryote genetic organisation and gene regulation requires that mutants affecting the regulation of adjacent genes of defined function be isolated and characterised. This communication describes a mutant of *Aspergillus nidulans* that is altered in a site closely linked to the structural gene (*amdS*) for acetamidase (EC 3.5.1.4)^{7,8} and results in increased inducibility of this enzyme by acetamide. It is further shown that this mutation is *cis*-dominant in its effects.

In *Aspergillus nidulans*, lesions in the gene *areA* can result in inability to utilise a wide variety of nitrogen sources, including acetamide⁹. This gene is probably involved in regulation of enzyme synthesis by ammonium (ref 9 and M J H, unpublished). Strains containing the mutation, *areA217*, grow very weakly on acetamide (and many other compounds) as the sole nitrogen source in the presence of glucose or acetate as sole carbon sources, but grow normally on acetamide as

the sole carbon source. The original mutant was isolated from a strain containing the *areA217* lesion as a N-methyl-N'-nitro-nitrosoguanidine-induced revertant which could grow strongly on medium containing acetate as the sole carbon source with acetamide as the sole nitrogen source.

Genetic analysis has shown that the mutant contains a lesion, provisionally designated *amdI9*, which is closely linked to *amdS*, the structural gene for acetamidase, and that it retains the *areA217* mutation. An *areA*⁺, *amdI9* derivative obtained by crossing to a wild type strain, has been used extensively in further analyses.

*Present as sole nitrogen sources (10 mM) in glucose-minimal medium.

†Present as sole carbon and nitrogen source (50 mM).

The *amdI9* lesion results in increased growth on acetamide, either as a carbon or as a nitrogen source (Table 1), but does not affect growth on other nitrogen sources. Acrylamide is a non-inducing substrate for acetamidase¹¹. Therefore the finding that strains containing *amdI9* do not grow better than *amdI*⁺ strains on acrylamide as the sole nitrogen source in glucose medium, indicated that inducibility of the acetamidase might be affected by *amdI9*. The enzyme results shown in Table 2 support this proposal. Strains containing *amdI9* have higher acetamidase activities than *amdI*⁺ strains under conditions of induction by acetamide but similar activities to *amdI*⁺ strains under non-induced conditions. Therefore *amdI9* appears to result in increased acetamidase induction by acetamide.

Table 2 Acetamidase activities of *amdI* strains

Mycelia for enzyme assays grown, extracted and assayed by methods described previously^{12,13}. Units of activity = nmol ammonium per min per mg protein.

*Mycelia grown for 16 h in glucose-10 mM ammonium medium and then transferred to these media for a further 4 h before harvesting.

To see if the effects of *amdI9* are limited to the *amdS* gene in the *cis* position it was necessary to obtain strains of genotype *amdI9, amdS*[−] (where *amdS*[−] represents a structural gene lesion) by isolating spontaneous mutants of *amdI9* strains which are resistant to fluoroacetamide. This technique readily yields *amdS*[−] mutants with low acetamidase activities⁷. In this way a number of *amdI9, amdS*[−] strains have been isolated. The presence of lesions in *amdS* was confirmed by complementation tests in heterokaryons and diploids with known *amdS*[−] mutants, as well as the finding of close linkage to known *amdS*[−] mutants. In the cases of the *amdI9, amdS*[−] mutants reported here, the retention of the *amdI9* lesion has been shown by the recovery of *amdI9, amdS*⁺ recombinants in crosses. Heterozygous diploids with *amdI9* in *cis* or in *trans* to *amdS*⁺ genes have been constructed and tested for acetamide utilisation and acetamidase activities (Table 3). The *amdI9* lesion is *cis*-dominant to *amdI*⁺ in such diploids, with strong growth on acetamide and elevated acetamidase activities occurring only when *amdI9* is *cis* to *amdS*⁺.

amdI9 strains produce an acetamidase that is indistinguishable from the enzyme of *amdI*⁺ strains in electrophoretic

mobility in starch gels, thermolability and substrate specificity (M J H, unpublished). This, together with higher enzyme levels found only under induction conditions, makes it likely that *amdI9* affects acetamidase regulation rather than structure. The simplest hypothesis to account for this data is that *amdI9* affects a regulatory site necessary for interaction with a regulatory molecule involved in induction by acetamide. This site is altered by the *amdI9* mutation such that inducibility is greatly increased. Although a number of possible regulatory genes affecting the acetamidase have been found (refs 7–9, 11, 13 and M J H, unpublished), it is not yet clear which of these is involved in induction by acetamide. The hypothetical regulatory molecule could have a negative action (repressor) and in this case *amdI9* would cause repressor binding to be weaker. Alternatively (and perhaps more likely) the regulatory molecule could have a positive action (activator), with *amdI9* allowing a more efficient activation of enzyme synthesis. Studies on the effects of *amdI9* on the general control mechanisms, such as ammonium repression and catabolite repression^{8,12,13}, which affect acetamidase, are in progress. These,

together with genetic fine structure analysis, should provide important information regarding the relationship between the regulatory sites influencing the activity of the adjacent structural gene.

Role of premeiotic replication in gene conversion

CURRENT molecular models of meiotic recombination have attempted to explain both classical reciprocal recombination (crossing over) and non-reciprocal intragenic recombination (gene conversion), with a single unified mechanism^{1,2}. An important assumption inherent in such models is that both types of recombination occur during the prophase following premeiotic chromosome replication. To date, however, only crossing over (chiasma) has been convincingly shown to occur during meiotic prophase³. Gene conversion, which has been most extensively studied in the ascomycete fungi⁴, has, for a number of cogent reasons⁵, also been assumed to occur during prophase, yet direct evidence supporting this critical point is lacking. In fact, in an important paper⁶, concerning recombination in yeast, evidence was presented indicating that intragenic recombination and premeiotic replication coincided, a finding which argues against much current speculation. To clarify this situation we simultaneously measured premeiotic replication and gene conversion in the yeast *Saccharomyces cerevisiae*, and examined the genetic consequences of inhibiting DNA synthesis with hydroxyurea (HU). We show that during the premeiotic S phase cells acquire a 'potential' for completing gene conversion, but that the actual formation of stable intragenic recombinants occurs after replication and depends on a period of postreplicative DNA synthesis.

In yeast, meiosis is induced by transferring logarithmically growing cells to nitrogen-free sporulation medium⁷. The kinetics of various meiotic events are shown for diploid strain 4579 (Fig. 1a). Since this strain is heteroallelic for a non-complementing pair of mutations at the *leucine-2* locus

gene conversion could be monitored by the appearance of prototrophic recombinants (+ +) on leucine-free selective medium. The *leu2-1* and 2-27 alleles were chosen because genetic analysis⁸ revealed that prototrophs arose by gene conversion rather than by reciprocal recombination. The recovery of prototrophs coincided rather closely with the period of premeiotic replication (6-15 h) (Fig. 1a). Data from seven experiments correlating the extent of DNA synthesis with the recovery of recombinants are given in Fig. 1b, clearly showing the close temporal relationship between the two events. Coincidence between replication and intragenic recombination was also seen in diploids heteroallelic for *arginine-4*, *leucine-1*, *uracil-3*, and *adenine-8*. Sporulation, which signals the completion of meiosis, extended within the population from 14-30 h.

We considered two alternative explanations for the temporal coincidence between replication and the recovery of gene convertants: (i) gene conversion occurs during premeiotic replication, or (ii) premeiotic replication coincides with 'commitment' of the cell to a developmental pathway which includes gene conversion, but the actual conversion event takes place later, during the postreplicative interval. The second alternative exists because of the indirect way in which recombination is measured; in practice, conversion is detected by counting prototrophic colonies which appear several days after meiotic cells are plated on selective medium. Thus the exact time of formation of a recombinant gene is obscured⁹, conceivably it could have been many hours after a 'committed' cell was first plated on selective medium.

To distinguish between the two alternatives we used hydroxyurea (HU), a specific reversible inhibitor of DNA synthesis¹⁰. We reasoned that if recombinants were actually generated

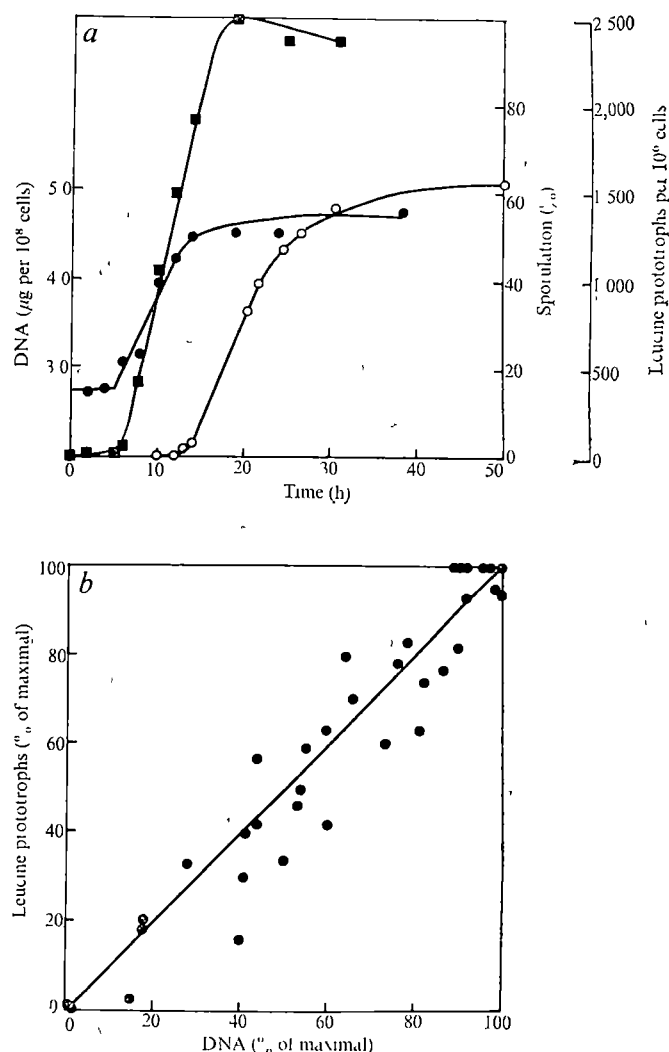

Fig. 1 Coincidence between recovery of gene convertants and replication during meiosis. Strain 4579 has the following genotype

<i>his4</i>	<i>leu2-1</i>	+	<i>α</i>	<i>thr4</i>	<i>ade2</i>	<i>met2</i>	<i>ura3</i>
+	+	<i>leu2-27</i>	<i>a</i>	+	<i>ade2</i>	<i>met2</i>	<i>ura3</i>

Media and procedures used for growth and induction of meiosis (sporulation) were previously described¹⁴; incubations were at 30°C. a, At zero time (*t* = 0) a growing culture was collected, washed, and suspended in acetate sporulation medium. At intervals, samples were removed to measure simultaneously (i) DNA synthesis per cell (●), (ii) the frequency of leucine prototrophic recombinants (■), and (iii) the percentage of asci (○). DNA was determined using a semimicro modification of the procedure of Croes¹⁵ (details to be published elsewhere). Leucine prototrophs were monitored by plating diluted culture samples on to leucine-free synthetic medium¹⁴. Ascus formation was determined by phase contrast microscopy. b, Data from seven independent experiments relating DNA synthesis and prototroph recovery were combined, as follows: for each experiment the total increase in DNA between *t* = 2 h and *t* = 36 h was set equal to 100%, similarly the maximal increase in prototrophs over this interval was also set to 100%. For each experimental point the percentage increase in DNA was plotted against the corresponding value for the increase in prototrophs.

during replication, then exposure to HU after replication was complete would not affect those recombinants already formed. In contrast, if gene conversion followed replication, then HU added to cells after replication might inhibit recombination by interfering with the localised, repair-type DNA synthesis which would be necessary for gene conversion¹¹.

In preliminary experiments we demonstrated that 100 mM HU inhibited both the initiation and continuation of DNA synthesis in meiotic cells. But, increases in mass, and protein

and RNA synthesis continued in essentially normal fashion (for up to 18 h) in cultures treated with HU. Thus, in meiotic cells as in mitotic cells¹⁰, HU selectivity inhibited DNA synthesis. The effects of HU on recombination are shown in Fig 2, addition of the drug before replication completely blocked the appearance of meiotic recombinants, however, the low frequency of leucine prototrophs pre-existing in the population was not affected. When HU was added any time during replication, recombination was quickly halted, in addition, with continued incubation in HU there followed a rapid and extensive decline in the number of recombinants initially present at the time of drug addition. Eventually, the rapid loss of recombinants stopped, and their frequency reached a stable value which depended on the time of drug addition. As shown in Fig 2 the decline in recombinants could not be attributed to a generalised toxic effect: viability even after prolonged drug exposure was > 95% HU, added during replication, caused similar declines in the number of recombinants in diploids heteroallelic for unrelated loci (for example *arg-4*, *leu-1*, and *ura-3*). In no case could the decline be attributed to losses in viability.

Was the dramatic HU-induced decline in recombinant frequency associated with inhibition of ongoing chromosome replication (the premeiotic S phase), or with inhibition of postreplicative DNA synthesis? To answer this we had to determine the time when premeiotic S phase was completed in the asynchronous population of developing cells. Completion of replication was evaluated by blocking DNA synthesis (with HU) at various times and examining the ability of inhibited cells to complete meiosis, as judged by the formation of mature asci (Fig 3). We considered sporulation a functional test for the completion of replication. Curve *a* of Fig 3 depicts the final percentage of asci obtained in HU-inhibited cultures plotted against the time of drug addition. Presumably, curve *a* represents the kinetics of completion of replication in the population. Comparing curve *a* with the effects of HU on

Fig 3 Effects of hydroxyurea on sporulation. A meiotic culture of 4579 was established as in Fig 1. Sporulation in this culture (● = control), is shown as curve *b* (solid line). At the times indicated on the figure (and at $t = 0, 3, 7$, and 9 h, detailed data not shown), portions of the control culture were transferred to separate flasks containing HU (final concentration = 100 mM). During subsequent incubation in HU, samples from each culture were removed, fixed in formaldehyde, and scored for percentage sporulation; these data are shown as a series of broken lines. Note that after prolonged incubation in HU the percentage of asci begins to decline. In curve *a* (□), the maximal level of sporulation reached in each of the HU-treated cultures is shown plotted against the time when the cells were first exposed to the drug.

Fig 2 Effects of hydroxyurea on meiotic gene conversion and viability. A meiotic culture of 4579 was established as in Fig 1. Recovery of prototrophs in the control culture (●) is shown as a solid line. At the times indicated on the figure, portions of the control culture were transferred to separate flasks containing sufficient 2.5 M hydroxyurea to yield a final concentration of 100 mM. During subsequent incubation in HU, samples from each culture were plated to determine the frequency of remaining prototrophs; these values are shown as a series of broken lines. For simplicity, the maximal prototroph frequency in the control was set to 100%, and the absolute frequencies of prototrophs in the HU-treated cultures were converted to percentages of this value. Hydroxyurea (Squibb) was dissolved in H₂O, and filter sterilised just before use. Inset: effects of extended HU exposure on survival of meiotic cells. At $t = 5$ h and $t = 12$ h, portions of a meiotic culture (control) were transferred to flasks containing HU (final concentration = 100 mM). At intervals, samples from the control and HU-treated cultures were removed, sonicated briefly to disrupt clumps, diluted, and plated on complete medium¹⁴. Colonies were counted after 5 d. ●, Control, ○, HU at $t = 5$ h, □, HU at $t = 12$ h.

recombination (Fig 2), revealed that the fraction of cells (relative to the control frequency) which completed replication was far in excess of the fraction of cells which formed stable (HU-resistant) recombinants. For example, at $t = 12$ h ~ 1/3 of the cells had completed replication, yet addition of HU at this time revealed that of the apparent recombinants (55%) only 5% were stable. This suggests that gene conversion cannot be consummated during the premeiotic S phase, but only later. In addition, the sensitivity of recombination to HU, in cells which have completed replication, indicates that successful gene conversion requires some postreplicative DNA synthesis.

Our conclusion that gene conversion occurred after replication depended on at least two assumptions: (i) that HU acted quickly to stop replication, and therefore, gave an accurate estimate for the time of completion of replication, and (ii) that ascus formation in HU is a valid functional test for the presence of a fully replicated genome.

To confirm independently that HU could provide an accurate estimate of the completion of replication (Fig 3) in a population, we examined the consequences of blocking DNA synthesis using one of Hartwell's temperature-sensitive replication defective mutations¹². Strain Z-198 (Fig 4) is homozygous for a thermal lesion in gene *cdc8*, which controls a step required for DNA polymerisation. During meiosis, a shift from a permissive temperature (23°C) to a restrictive temperature (34.5°C) immediately blocked replication. A culture of Z-198 was grown and transferred to sporulation medium at 23°C, at intervals duplicate samples were either shifted to 34.5°C, or put into HU at 23°C (Fig 4). The final percentage sporulation attained plotted against the time of the HU or high-temperature challenge are compared in Fig 4. Both treatments yielded virtually identical curves, and thus, provided the same estimate for the time of completion of replication in the population.

Fig. 4 Effects of hydroxyurea and restrictive temperature on sporulation of strain Z-198

Thermosensitive strain Z-198 has the following genotype

<i>cdc8-1</i>	<i>ura1</i>	<i>his4</i>	<i>leu2</i>	<i>a</i>	<i>thr4</i>	<i>ade2</i>	<i>tyr1</i>
<i>cdc8-1</i>	<i>ura1</i>	+	+	<i>a</i>	+	+	+
<i>his7</i>	<i>lys2</i>	+	+	<i>ade1</i>	+		
+	-	<i>met2</i>	<i>trp5</i>	<i>ade1</i>	<i>gal1</i>		

It was constructed by mating Hartwell's *cdc8-1* parent strain¹² to a thermoresistant haploid of opposite mating type (*x1069-2D*), and selecting for a thermosensitive mitotic segregant following a sublethal dose of ultraviolet irradiation¹⁶. Homozygosity for *cdc8-1* was confirmed by complementation tests¹³. A meiotic culture of Z-198 was established as in Fig. 1, except that growth and sporulation of the control culture were conducted at 23°C. Premeiotic DNA synthesis (●), and sporulation (○), were determined as in Fig. 1. At intervals during meiosis duplicate samples were removed from the control culture and transferred, either to a flask prewarmed and maintained at 34.5°C, or to a flask maintained at 23°C, but containing HU (100 mM). Sporulation was monitored for an extended period (48 h) in each of the HU and heat-treated cultures. The maximal percent sporulation reached in each culture is shown plotted against the time when the cultures were first exposed to the HU (▲) or the restrictive temperature (□).

Evidence that the asci formed in HU contained viable ascospores was obtained as follows: meiotic cells (of strain 4579) were exposed to HU, at $t = 12$ h, and allowed to complete sporulation in the presence of the drug. The resulting asci were dissected, and the individual spores tested for survival on complete medium¹³. Viability for the HU-treated asci (86%), was similar to that in mature asci from a control culture never exposed to the drug (90%). Thus asci formed in HU contained viable haploid cells, presumably originating by replication of the original diploid genome.

Our primary objective was to reconcile data which suggested that gene conversion might coincide with replication, and current molecular models which assume that conversion (as well as reciprocal recombination) takes place after replication, during meiotic prophase. We have shown that while 'potential' intragenic recombinants are recoverable during premeiotic replication, stable recombinants are only formed considerably after the premeiotic S phase. These results are entirely consistent with current models.

Increased sensitivity of lymphocyte Δ^1 -pyrroline-5-carboxylate reductase to inhibition by proline with transformation

THE mitogen-induced transformation of resting lymphocytes to proliferating blast forms is associated with a marked increase in amino-acid uptake¹, protein synthesis² and enzyme activities³. There is little information, however, on the effect of transformation on enzymes of amino-acid metabolism. We therefore examined the biosynthetic and degradative enzymes of the non-essential amino acid, proline⁴, in resting and transformed lymphocytes. We found a selective increase of proline biosynthetic enzymes in association with transformation. It is interesting that transformation also produced qualitative changes in Δ^1 -pyrroline-5-carboxylate reductase, the enzyme which catalyses the committed step in proline synthesis.

Lymphocytes from normal human donors were prepared routinely by dextran sedimentation of heparinized whole blood or by separation of whole blood on Ficoll-Hypaque gradients. The collected leukocytes were then washed in balanced salt solution and cultured at a cell density of 0.5×10^6 mononuclear leukocytes per ml of RPMI 1640 medium supplemented with 10% autologous plasma, 4 mM glutamine, penicillin (50 U ml⁻¹) and streptomycin (50 μ g ml⁻¹). In each experiment half the cells were cultured with phytohemagglutinin (Burroughs Wellcome) at a concentration of 1 μ g ml⁻¹ (optimum concentration of this preparation as determined by thymidine incorporation) and are referred to as PHA cells, the remaining cells were cultured without PHA and are referred to as control cells. After specified periods of culture, cells were collected by centrifugation, washed three times in balanced salt solution at 4°C and disrupted by sonication in 1 ml of buffer appropriate for each enzyme assay. Enzyme activities of the lymphocyte sonicates were determined by radioisotopic assay methods as previously described⁵⁻⁸. Protein was determined by the method of Lowry⁹. In all instances enzyme specific activity is expressed as nmol product per h per mg protein.

PHA transformation produced marked changes in the enzymes of proline biosynthesis (Fig 1). Twelve hours after the addition of PHA the specific activity of the proline biosynthetic enzyme, Δ^1 -pyrroline-5-carboxylate reductase (PCA reductase), began to increase considerably. Seventy-two hours after the addition of PHA, the specific activities of the biosynthetic enzymes, ornithine- δ -transaminase (OTA) and PCA reductase, increased to levels at least fifteen times those in either cultured control cells or fresh peripheral lymphocytes. In contrast, the proline degradative enzymes did not follow this pattern. With 72 h of PHA-stimulated mitogenesis, the specific activity of PCA dehydrogenase remained unchanged while proline oxidase activity remained undetectable in either sonicates or mitochondrial preparations. For proline oxidase we used a radioisotopic method able to detect less than 5 pmol of product. Thus, only the biosynthetic enzymes of proline metabolism are increased with lymphocyte activation.

The marked increase in PCA reductase was of special interest to us. We showed previously that PCA reductase exists in two forms: one sensitive and one insensitive to feedback inhibition by proline¹⁰. Enzyme obtained from resting cells in animal tissues (rat liver, brain, kidney) is relatively insensitive to proline inhibition with less than 50% inhibition at 10^{-2} M proline. In contrast, PCA reductase from cells growing in culture (human fibroblasts, Chinese hamster ovary and lung cells and rat liver cells) is always markedly sensitive to proline inhibition with 50% inhibition at 2×10^{-4} M proline. Thus we considered whether the increase in PCA reductase in the transformed lymphocyte would be accompanied by a change in the proline sensitivity of the enzyme. Figure 2 shows the proline inhibition

Fig 1 Effect of phytohaemagglutinin (PHA) transformation on the enzymes of proline biosynthesis and degradation. Data are expressed as percentage change over control cells incubated without PHA. Each point represents the mean of at least three determinations performed on extracts from three separate cultures. PCA reductase (○), ornithine transaminase (●), PCA dehydrogenase (□), proline oxidase (■).

of PCA reductase from control and PHA cells after culture for 72 h. The control cell enzyme was relatively insensitive to proline being inhibited only about 30% by 10^{-3} M proline. The same curve of proline inhibition was obtained when either fresh peripheral lymphocytes or cells purified to greater than 99% lymphocytes were the enzyme source. In contrast, the PHA cell enzyme was markedly more proline-sensitive, with 50% inhibition by 2×10^{-4} M proline and 85% inhibition by 10^{-3} M proline. Clearly in addition to a 15-fold increase in specific activity with lymphocyte transformation, PCA reductase became markedly more sensitive to inhibition by proline. The slight inhibition of the control enzyme by proline may have resulted from the presence of a small amount of the proline-sensitive form of the enzyme in resting lymphocytes or from the presence of 1–2% activated lymphocytes in the control cell population.

The marked difference in proline sensitivity of PCA reductase

Fig. 2 Proline inhibition of PCA reductase. PCA reductase activities in extracts of 72-h PHA cells (○) and 72-h control cells (●) were assayed with various concentrations of proline. The assay mixture included Δ^1 -pyrroline-5-carboxylate, 0.045 mM (in the L configuration), NADH, 0.68 mM, phosphate buffer 0.1 M, pH 6.8, and 20 μ g of extract protein. The mixture was incubated at 37°C for 10 min. Each point represents the mean \pm s.e.m. of three determinations performed on extracts from three cultures.

in 72-h transformed lymphocytes may represent the selective synthesis of proline-sensitive PCA reductase. In support of this hypothesis, we found that the time course of change in sensitivity to inhibition by proline paralleled the increase in PCA reductase activity, both showing a 12-h lag after addition of PHA. Furthermore, the total increase in PCA reductase specific activity with transformation represents an increase only in the proline-sensitive activity. The proline-insensitive activity (activity in the presence of 1×10^{-3} M proline) did not change significantly during 72 h of PHA transformation.

If the observed 12-h lag was related to the synthesis of mRNA coding for the proline-sensitive reductase and subsequent accumulation of the new enzyme, we should have been able to block the appearance of the enzyme with inhibitors of RNA and protein synthesis. When either actinomycin D (5 μ g ml⁻¹) or cycloheximide (0.05 mM) was added to PHA cells at time zero and cells were collected 18 h later, both the increase in PCA reductase activity and the appearance of proline sensitivity were blocked (Fig 3). The PCA reductase activity of control cells was unaltered by a comparable exposure to inhibitors. Furthermore, actinomycin D added 8 h after addition of PHA in an otherwise similar experiment (data not shown) did not prevent increases in either PCA reductase activity or sensitivity to inhibition by proline. Therefore, these alterations in PCA reductase activity require both RNA and protein synthesis.

Fig. 3 The effect of actinomycin D and cycloheximide on PHA-induced increases in PCA reductase. Lymphocytes were cultured for 18 h with PHA, PHA plus actinomycin D, (5 μ g ml⁻¹) or PHA plus cycloheximide (0.05 mM). The bars represent total enzyme activity whereas the cross-hatched areas represent activities in the presence of 10^{-3} M proline. Data represent the mean of at least three determinations performed on extracts from three cultures.

The most straightforward explanation of these data would involve the preferential synthesis of a proline-inhibitable isozyme of PCA reductase in association with the change from resting to actively growing lymphocytes. This hypothesis is consistent with our work demonstrating the occurrence of proline-insensitive PCA reductase in resting cells obtained from animal tissues and proline-inhibitable reductase obtained from cells adapted for rapid growth in tissue culture¹⁰. Confirmation of this hypothesis will require direct demonstration of two forms of PCA reductase.

The accumulation of a proline-sensitive PCA reductase is beneficial to the activated lymphocyte in two ways. The proline synthetic capability is increased to meet the demands of increased protein synthesis and the proline sensitivity of this enzyme makes proline synthesis subject to negative feedback control. Thus, in the activated lymphocyte if exogenous proline were adequate to meet the demands of increased protein synthesis, PCA reductase would be inhibited, sparing proline precursors for use elsewhere in the cell.

Human immunoglobulins with a1 allotypic determinants of rabbit immunoglobulin heavy chains

ALLOTYPIC genetic variations in the variable (V) part of immunoglobulin (Ig) chains have been clearly identified only in the domestic rabbit. Three allotypic specificities, a1, a2 and a3, controlled by allelic genes, *a*¹, *a*² and *a*³, at the *a* locus, are present on the variable region of heavy chains of all classes (IgM, IgG, IgA and IgE)¹⁻³. These allotypic specificities reflect multiple amino acid differences in the V region of Ig heavy chains⁴.

Subgroups also differ in the amino acid sequence in the V region. The heavy chains bearing the specificities controlled by the *a* locus represent a heavy chain subgroup designated V_Ha which accounts for 70-90% of the Ig heavy chains in the rabbit. The N-terminal amino acid sequence of pooled Ig heavy chains of the V_HIII subgroup from each of nine different species (including cat, dog, human, mouse, rat, guinea pig, mink, seal and sea lion), revealed striking similarities⁵. With one exception (cat), the sequence in any species did not differ from the sequence in any other species by more than four of the N-terminal 24 amino-acid residues⁵. Also, Rodkey and

Hansen⁶ found that some of the a2 and a3 allotypic specificities are present on the Fab fragment of IgG from cottontails and jack rabbits which are species closely related to the domestic rabbit. These observations led us to investigate whether anti-allotypic antisera, directed against the allotypic specificities present on the V part of rabbit heavy chains would react with human immunoglobulins. This report deals with the reaction of anti-a1 anti-allotype antiserum with human IgG (Hu IgG).

Pooled Hu IgG (FR II, Pentex, Kankakee, Illinois) was labelled with ¹²⁵I (ref. 7) and tested for the presence of the a1, a2 and a3 determinants by an indirect precipitation assay. Rabbit anti-a1, anti-a2 or anti-a3 antiserum was added to 0.1 µg ¹²⁵I-IgG, after 30 min at 37° C, goat anti-rabbit IgG antiserum (previously adsorbed with a Sepharose immunosorbent containing Hu IgG) was added to precipitate the complexes formed by the reaction of the anti-allotype antiserum and the ¹²⁵I-Hu IgG. After 24 h, the resultant precipitate

Table 1 Percentage precipitation of ¹²⁵I-labelled rabbit IgG or Fab_γ by rabbit anti-a1 antibody eluted from a Sepharose immunosorbent containing human IgG

Rabbit	Allotypes	¹²⁵ I-antigen	Radioactivity precipitated (%)
H209-3	a1,b5	IgG	85
		Fab _γ *	67
2L280-3	a1,b5	Fab _γ	75
F280-3	a1,b5	IgG	81
		Fab _γ	62
L244-1	a1,b5	IgG	89
		Fab _γ	68

03485	a3,b5	IgG	3

*The Fab_γ fragments were prepared by papain digestion of IgG followed by CM-cellulose chromatography as described by Porter¹³, the Fab I fragments were used as the antigens.

was washed, the radioactivity in the supernatant fluids and in the precipitates was determined and the percentage radioactivity precipitated was calculated⁸. Anti-a1 precipitated 71% of the radioactivity of the Hu IgG whereas anti-a2 and anti-a3 precipitated less than 5% of the radioactivity.

Those anti-a1 antibody molecules which reacted with Hu IgG were isolated from a Sepharose immunosorbent column containing pooled Hu IgG⁹. The anti-a1 antibody, reacting with Hu IgG, was used for the analysis of Hu IgG samples.

Hu IgG was isolated from serum samples of nine individuals by a combination of salt precipitation with Na₂SO₄ and DEAE-cellulose chromatography^{10,11}. The purified IgG samples were labelled with ¹²⁵I (ref. 7) and were shown to be more than 95% Ig by quantitative precipitation with rabbit anti-Hu IgG. These labelled IgG samples were reacted with the specifically purified anti-a1 by the quantitative radioprecipitation assay described above, from 45 to 70% (average, 61%) of the radioactivity was precipitated. In controls where normal (unimmunised) rabbit serum was substituted, for anti-a1 less than 9% of the radioactivity was precipitated.

To determine if the a1 specificity present on Hu IgG was a genetic variant or was present in all individuals, plasma samples from 270 individuals were tested for the presence of a1 specificities by a quantitative inhibition of precipitation assay¹². The 270 plasma samples were obtained from the clinical laboratories of our University Hospital and 5γ of a plasma sample was added to a tube containing 0.05 µg ¹²⁵I-Hu IgG (from an individual). An amount of anti-a1 that was slightly less than that needed to precipitate all of the ¹²⁵I-Hu IgG was added and the tubes were incubated for 30 min at 37° C, then, goat anti-rabbit IgG was added to precipitate the anti-a1 and any Hu IgG bound to the anti-a1. The percentage radioactivity precipitated was determined and the percentage in-

Table 2 Percent precipitation of ^{125}I -labelled human Fab_γ and F(ab')_2 fragments by anti-a1 anti-allotype antibody, anti-Hu IgG antiserum and anti-Hu Fc_γ antiserum*

Person	Labelled fragment	Precipitation by antibody to		
		a1 %	Hu IgG %	Hu Fc_γ %
WJH	F(ab')_2	36	79	1
UNK	Fab_γ	40	90	3

*Anti-Hu IgG has antibodies directed toward light chains and heavy chains. Anti-Hu IgG was made specific for determinants on the Fc part of IgG by passing the antiserum through a Sepharose immunosorbent column containing F(ab')_2 fragments of normal pooled human IgG

hibition was then calculated for each plasma sample. All 270 plasma samples completely inhibited the reaction of anti-a1 with Hu IgG, thus, all of the human sera tested possessed the a1 specificity.

That the specifically purified anti-a1 still reacted with the a1 determinants of the rabbit was shown by its ability to react with most (81–89%) of the IgG molecules as well as with the Fab_γ fragment obtained from rabbits with the genotype $a^1a^1b^5b^5$ (b^4 and b^5 are allelic genes at the b locus, these genes control the synthesis of rabbit b4 and b5 light chains, respectively). The purified anti-a1 did not precipitate the IgG molecules obtained from two $a^2a^2b^5b^5$ rabbits nor from one $a^3a^3b^5b^5$ rabbit (Table 1). These assays were done by the quantitative precipitation analysis as described above except that anti-b4, rather than goat anti-rabbit IgG, was used as the indirect reagent (the anti-a1 had been prepared in a b^4b^4 rabbit thus permitting the use of anti-b4 as an indirect reagent).

Human Fab_γ fragment was prepared by papain digestion¹⁴ of Hu IgG obtained from one individual (UNK) and F(ab')_2 fragment was prepared by pepsin digestion¹⁵ of Hu IgG obtained from another individual (WJH). Analysis of these fragments by the radioprecipitation assay revealed that the a1 determinant is present on the Fab_γ (40%) and the F(ab')_2 (36%) fragments (Table 2) as well as on the intact IgG (47%) of WJH. That the F(ab')_2 and the Fab_γ fragments were not contaminated with Fc fragments is shown by the observation that anti- Fc_γ did not react with the F(ab')_2 nor with the Fab_γ fragments, that is, less than 5% of the radioactivity was precipitated (Table 2).

Not all anti-a1 antisera reacted with Hu IgG. Of the anti-a1 antisera obtained from 5 different rabbits (E208-3, K158-3, 53923, H207-2, and J314-1) only E208-3 and K158-3 reacted with Hu IgG. The explanation for this observation is currently not clear. As not all anti-a1 antisera reacted with Hu IgG, we have recently examined several different anti-a2 and anti-a3 antisera and have indeed found an anti-a2 and an anti-a3 antiserum which react with Hu IgG.

In conclusion, we have shown that Hu IgG molecules have at least one antigenic determinant of the rabbit a1 specificity. This a1 determinant in man was present in all 270 individuals tested, was found on at least 60% of the IgG molecules and was localised to the Fab fragment. Population studies with anti-a1 as well as with anti-a2 and anti-a3 purified rabbit antibodies reacting with human IgG should resolve the genetic basis for these determinants in man and indicate whether they are isotypic or allotypic antigenic determinants, that is, present in all individuals or segregated among the population as in rabbits. Studies with myeloma proteins of different classes and subgroups should be useful for the precise localisation and characterisation of these determinants in human immunoglobulins.

Uptake of environmental antigens by the bursa of Fabricius

THE bursa of Fabricius of birds has an essential role as a central lymphoid organ for the differentiation of B lymphocytes^{1,2}. In addition, the bursa harbours immunocompetent B cells³ which are capable of local antibody production. Haemolytic plaque-forming cells have been observed in the bursa after introducing sheep red blood cells (SRBC) into the bursal duct⁴. Furthermore, epithelial cells of the bursal follicles have been shown to transport ferritin and India ink into the intercellular spaces of the underlying lymphoid tissue when the material has been introduced into the bursal lumen⁵. The bursal lumen opens through the bursal duct to the most caudal of the three cloacal chambers, the proctodeum, which is of ectodermal origin^{6,7}. The proctodeum leads to the outside through the anus and is closed externally by a strong sphincter muscle. The vent is surrounded on the outside by upper and lower anal lips. At the other end, the proctodeum opens into urodeum leading to the coprodeum and these form the cranial parts of the cloaca (Fig. 1a).

During surgical bursectomy, we observed that the anal lips of a chicken make peristaltic movements as if sucking something into the cloaca. When a liquid or suspension was applied to the external parts of the anus, it was rapidly taken inside by these movements. We hypothesised that at least part of the sucked material could be taken into the bursa and that this phenomenon probably serves as a trapping mechanism for environmental antigens. To test the hypothesis we examined the macroscopic and microscopic fate of material applied to the anal lips, and whether antigen administration by this mechanism leads to an antibody production.

We placed 0.05–0.1 ml volumes of barium sulphate on the anal lips of 6-week-old White Leghorn chicks, and visualised the intake by X-ray pictures. It seemed that this contrast medium was actively sucked through the proctodeum and the bursal duct into the bursa. In all, about 2 ml of the medium was taken into the bursa in 3 min (Fig. 1b–e). Only negligible amounts of the contrast medium appeared in the urodeum and coprodeum. When applying the medium for the X-ray pictures presented here, the chicks were kept in a position with the anus upwards. In this position, most of the contrast medium was evacuated normally and the same results were obtained when the medium was applied to the anal lips of chicks in the normal position—even though this was technically more difficult.

To study the microscopic distribution of the material sucked by the bursa, 0.1–0.5 ml of India ink (Pelikan 17 noir, Gunther

Wagner, Germany, dialysed overnight against physiological saline) was applied to the anal lips of 4-week-old chicks as described above. The chicks were anaesthetised with ether, and the bursae removed at appropriate intervals for microscopic examination. Two minutes after the application, no carbon was observed in the bursal tissues, 15 min after the application, some fine carbon particles occurred superficially in the follicle-associated epithelium and after 2 h the tracer had spread throughout the follicle-associated epithelium (Fig 2a). The cylindrical epithelium lining the bursal lumen and not associated with the follicles was almost always free of the carbon. Six hours after the application, fine and coarse carbon granules were observed in the central part of the follicular medulla (Fig 2b). These findings demonstrate that material available on the anal lips makes intimate contact with the lymphoid cells in the bursa so that antigenic sensitisation by this route is possible.

Fig 1 a, Schematic presentation of the three cloacal chambers and the bursa of Fabricius in the chicken. A, anus, AL, anal lips, P, proctodeum, U, urodeum, C, coprodeum, B, bursa of Fabricius, T, tail. b-e, X-ray visualisation of barium sulphate applied on the anal lips. About 2 ml of the medium was sucked into the bursa in 3 min. Only negligible amounts appeared in the urodeum and coprodeum.

Fig 2 Bursal sections after application of dialysed India ink on the anal lips. a, 2 h after the application, carbon granules appear in the follicle-associated epithelium while the follicle is free of carbon, b, after 6 h, carbon has spread more widely and deeply into the follicle-associated epithelium, and carbon granules are observed also in the medulla of the follicle. Weak methylgreen nuclear staining ($\times 256$).

To examine whether the antigenic challenge through the bursa leads naturally to antibody production, 10^8 killed *Brucella abortus* organisms and 10^{10} SRBC in 0.1 ml of physiological saline were applied to the anal lips of 4-week-old chicks as in the experiments described previously. The procedure was repeated on six consecutive days. Blood samples from a wing vein were collected on the day after the final antigen administration. High serum antibody titres against a thymus-independent antigen³, *Brucella*, were observed, whereas serum antibody titres against the thymus-dependent SRBC were close to those found in unimmunised controls (Table 1). We interpret these findings to indicate that antigenic challenge *per bursam* leads to an effective antibody formation if no T-B-cell cooperation is required. This interpretation is supported by the vigorous antibody formation by transferred bursa cells against *Brucella* but not against SRBC in T and B-cell deficient recipients³.

On the basis of these findings, it is apparent that the immunological function of the bursa of Fabricius is not restricted to its inductive role in the B-cell differentiation but that it also has an important peripheral function. Furthermore, it is apparent that this peripheral function does not serve only local antibody production but leads to significant antibody titres in the blood. It remains to be established whether this antibody formation is restricted to that against thymus-independent antigens and whether it leads to formation of antibodies of different immuno-

Table 1 Serum antibody titres (mean \pm s.e.m.) after antigen application on the anal lips

Antigen*	No. of chickens	Log ₂ antibody titre†	
SRBC + <i>Brucella</i>	9	0.7 \pm 0.2	6.8 \pm 1.0
Saline	10	0.1 \pm 0.1	0.4 \pm 0.2

* 10^8 killed *Brucella abortus* organisms and 10^{10} SRBC in 0.1 ml were applied to the anal lips of 4-week-old chicks on six consecutive days.

†Serum antibody titres were determined from samples taken on the day following the final antigenic challenge, a microagglutination technique was used².

globulin classes in the same way as obtained after parenteral immunisation. It is also conceivable that constant presentation of environmental antigens in the newly-hatched period to the cells proliferating in the bursa leads to antigen-generated antibody diversity^{8,9}.

In conclusion, we suggest that a major function of bursa of Fabricius, in addition to its role as a central lymphoid organ, is to provide a chance for an early antigenic challenge by environmental antigens. The sucking function described here ideally serves this purpose.

This research was supported by grants from the Academy of Finland and the Sigrid Juselius Foundation, and is pursuant to a contract with the National Cancer Institute, Bethesda, Maryland.

Ly antigens as markers for functionally distinct subpopulations of thymus-derived lymphocytes of the mouse

THYMUS-DERIVED lymphocytes (T cells) have several functions¹⁻³, and in some instances it appears that two subpopulations of T cells interact to amplify their response^{4,5}. But recognition of the diverse functions and interactions of T cells has not been matched by the development of techniques for identifying and separating the different T-cell subpopulations involved. The ability to do so would greatly aid study of the many roles of T cells. We report here experiments with mice that show that antisera to different Ly alloantigens can identify functionally-distinct subpopulations of T cells.

The *Ly-1* and *Ly-2* loci (chromosomes 19 and 6) specify alloantigens expressed exclusively and invariably on mouse T cells⁶. Each locus has alternative alleles that determine the T-cell surface antigens *Ly-1.1* and *Ly-1.2*, and *Ly-2.1* and *Ly-2.2*, respectively.

The four corresponding Ly antisera were produced by alloimmunisation with T cells as described⁷ and were absorbed with syngeneic thymocytes, if necessary, to remove thymocyte auto-antibody⁸. The mice used were of the B6 strain (*Ly-1.2*, *Ly-2.2*), and of B6 congenic partner strains with phenotypes *B6/Ly-1.1* and *B6/Ly-2.1*.

Table 1 shows the proportions of peripheral lymphocytes, and of cortisone-resistant thymocytes (CRT), lysed by optimal concentrations of *Thy-1* (formerly θ) antiserum,

and by these Ly antisera in the cytotoxicity assay with rabbit complement (C). Ly antigens are present only on T cells, and we shall assume that all T cells are *Thy-1*⁺ (that is they carry *Thy-1* antigen), we have therefore expressed the results in Table 1 as proportions of T cells (*Thy-1*⁺ cells) lysed by each Ly antiserum (% T) as well as proportions of the total population (abs = absolute).

The higher proportion of cells lysed by anti-*Ly-1.2* serum compared with anti-*Ly-2.2* serum was highly reproducible (Table 1) and may signify that there are more *Ly-1.2*⁺ T cells than *Ly-2.2*⁺ T cells among the peripheral T-cell population of B6 mice. This difference could also be explained, however, by differences in the constitution of the particular *Ly-1.2* and *Ly-2.2* antisera used (for example by different proportions of C-fixing antibody compared with other classes of antibody) and therefore more evidence is required on this point.

To determine whether T cells with different functions could be distinguished by characteristic Ly phenotypes, three functional assays for T cells were performed with cell populations pretreated with each Ly antiserum and C under essentially the same conditions as those of the C-dependent cytotoxicity assay⁹. We assayed (a) helper function of spleen cells from mice primed with sheep red blood cells (SRBC), (b) cell-mediated cytotoxicity (CMC) of non-adherent peri-

Fig 1 Effect of pretreatment with different anti-Ly sera and C on the helper function of spleen cells. Three mice were injected intravenously with 0.1 ml of 0.01% (v/v) SRBC. After 4 d their spleen cells were pooled and pretreated with Ly antisera and C (see below). Cultures were prepared containing these pretreated primed cells together with unprimed cells in various proportions (as indicated), maintaining a constant total 1×10^7 cells per culture. The cultures were sensitised with trinitrophenol (TNP)-conjugated SRBC and assayed 4 d later for TNP-specific PFC^{11,12}. For pretreatment, equal volumes of cells (5×10^6 ml⁻¹), antiserum (1/20) and complement (rabbit serum preabsorbed with mouse cells in the presence of EDTA) (1/6) were incubated in 5% CO₂ in air for 45 min at 37°C. These are the standard conditions for the C-dependent cytotoxicity assay⁹ (see Table 1). The diluent was Earle's balanced salt solution with 2.5% foetal bovine serum, 100 U ml⁻¹ penicillin, 100 µg ml⁻¹ streptomycin and 5×10^{-5} M 2-mercaptoethanol. A control for serological specificity (not shown) was substitution of *B6/Ly-1.1* (congenic) spleen cells for *B6/Ly-1.2* spleen cells, in this case pretreatment with anti-*Ly-1.2* serum and C gave no suppression of helper cell function. ○, Anti-*Ly-2.2*, ●, diluent only, ▲, anti-*Ly-1.2*.

Table 1 Cytotoxicity assays of Thy-1 and Ly antisera on various cell populations of B6 and B6/Ly-congenic mice

Serum anti-	Cells from	Titre on thymocytes (reciprocal)	Thymocytes	CRT		% Cells lysed* Lymph node cells		Spleen cells		NAPC	
				abs	% T	abs	% T	abs	% T	abs	% T
Thy-1 2	B6	10,240	>90	>90	100	66	100	32	100	39	100
Ly-1 2	B6	80	>90	75	83	57	86	27	84	29	74

Ly-1 1	B6/Ly-1 1	2,560	>90					26	81	30	77
Ly-2 1	B6/Ly-2 1	1,600	>90					10	31	8	21

CRT, cortisone-resistant thymocytes from mice given 1.5 mg of cortisone acetate intraperitoneally 24 h previously, abs, percentage of total population (absolute), % T, percentage of Thy-1⁺ cells present

* Figures corrected for background of dead cells by the formula $[(a-b)/b] \times 100$ where a is percentage cells viable in control (reciprocal) antiserum with C, or normal mouse serum (NMS) with C (always >90%), and b is percentage cells viable in cytotoxicity assay with antiserum and C

toneal cells (NAPC) from H-2-primed mice, and (c) graft-versus-host reactivity (GvH) of unprimed spleen cells

(a) The results of a typical assay of helper cell activity are shown in Fig 1. Helper function was virtually abolished by cytolysis of the SRBC-primed spleen cell population with anti-Ly-1 serum (specificity anti-Ly-1 2), whereas cytolysis with anti-Ly-2 serum (specificity anti-Ly-2 2) had no effect on helper function.

(b) In the CMC assay with peritoneal cells (NAPC) from allo-immunised (H-2-primed) mice the effect of the two Ly antisera was reversed. There was no suppression or only minimal suppression of CMC by pretreatment with anti-Ly-1 2 and C, whereas pretreatment with anti-Ly-2 2 and C strongly suppressed this ('killer cell') function¹⁰.

(c) The GvH (Simonsen) assay differs from the two preceding functional tests in that it involves initiation as well as implementation of the immune response. Both Ly-1 2 and Ly-2 2 antisera suppressed the GvH response of adult unprimed parental spleen cells inoculated into newborn F₁ hybrid recipients, as measured by Simonsen's spleen weight index.

Thus elimination of a proportion of T cells lysed by a particular Ly antiserum does not produce equivalent losses of different T-cell functions, and different Ly antisera eliminate T cells with different functions.

In these experiments the helper population was rich in Ly-1 and poor in Ly-2, and the reverse was the case with T cells responsible for CMC. The population involved in initiation and/or implementation of GvH evidently involves T cells expressing both Ly types, or more probably T cells of two Ly categories.

Table 2 Effect of pretreatment with anti-Ly sera and C on the cell-mediated cytotoxicity (CMC) function of non-adherent peritoneal cells (NAPC) from H-2-primed donors

NAPC* donors	Pretreatment†	CMC %I	
		Experiment 1	Experiment 2
Non-immune	Diluent only	0	0
Immune	Diluent only	50	76
Immune	NMS + C	64 (Standard)	78
Immune	Anti Ly-1 2 + C	65	67
Immune	Anti Ly-2 2 + C	28	30

* B6 donors received a single intraperitoneal injection of 10⁶ BALB/c (immune) or B6 syngeneic (non-immune control) spleen cells in Experiment 1 and multiple intraperitoneal injections of 5 × 10⁶ BALB/c (immune) or B6 syngeneic (non-immune) spleen cells in Experiment 2. NAPC were collected 5 d after an injection in Experiment 1 and 3 d after the last injection of four consecutive weekly injections in Experiment 2.

† See footnote Fig 1.

‡ ³H-proline CMC micro-assay^{13,14} in which the radioactivity of surviving attached monolayer target cells is measured. Washed NAPC (pretreated as in Fig 1, 1 × 10⁵ per well) were applied to a ³H-proline-labelled monolayer of BALB/c Meth A sarcoma cells (1 × 10³ per well) for 14 h. CMC % was calculated from the c.p.m. of the washed surviving monolayers after exposure to (a) Immune NAPC or (b) non-immune (control) NAPC, according to the formula $[1-(a/b)] \times 100\%$.

Table 3 Effect of pretreatment with different Ly antisera and C on the GvH capacity of spleen cells in the Simonsen assay¹⁵

Pretreatment of spleen cells†	Spleen indices of individual recipients†	Mean
None	1 98, 1 78, 2 03, 2 18 2 82, 2 21, 2 91, 3 28	2 44
Anti-Ly-1 2 + C	1 33, 1 67, 1 80, 1 08 0 95, 1 09, 1 14, 1 13 1 50, 1 21, 1 46, 1 75	1 27
Anti-Ly-2 2 + C	1 42, 1 42, 2 67, 1 57 1 81	1 64

* See legend to Fig 2.

† 1 × 10⁶ normal B6 spleen cells (pretreated as in Fig 2) were injected intraperitoneally into 1-5-d-old (B6 × BALB/c) F₁ hybrids. Spleen weight indices were calculated 9 d later according to Simonsen.

In addition to their implication with regard to the diversity of T cells, our findings suggest a means of isolating T-cell subsets with particular functions according to their Ly profiles. At the moment this can be said safely only of the B6 mouse with which these experiments were conducted, it remains to be seen whether the Ly profiles established for T-cell functions of this strain will prove to be representative of all mice.

January 24, 1975

There's more to telecommunications . . .

THE Science Research Council (SRC) has recently come out with a report by one of its specialist subject panels which deserves a wide readership, both because it raises some fundamental issues about scientific research in universities and because the topic with which it deals—telecommunications—plays such an intimate part in everyday life. The report considers the SRC's own support for telecommunications research in universities and polytechnics, and does some plain speaking about the nature of the research itself and the environment in which it is carried out (*Telecommunications*, Science Research Council, State House, High Holborn, London WC1R 4TA).

First of all, the panel contends that the emphasis in university telecommunications research is in the wrong place. Basically long-term work on, for example, signal processing and systems studies is eschewed, the panel says, in favour of transmission and propagation studies: as a rough guide 15 out of 31 SRC research grants current in June 1974 were for work on transmission lines, waveguides, antennas and propagation. On the other hand only three grants were awarded for studies of communications networks.

The drift of the panel's recommendations, which the SRC is putting about for discussion and comment, is not hard to guess. It wants the SRC to make a gradual transfer of funds to the research topics it highlights as 'special areas'. It also thinks that "existing university effort [in telecommunications research], with one or two exceptions, is too thinly distributed to be effective for the broader inter-disciplinary research required . . ." In other words, the SRC is being asked to implement its formula of selectivity and concentration.

The panel adds a rider, however, to the effect that there should still be funds available for "individual workers" to research on "limited aspects" of telecommunications. It says, however, that it does not want to see unnecessary duplication of work done, for example, at its own Appleton Laboratory (formerly the Radio and Space Research Station).

As far as research in universities in general is concerned there are two main questions that arise—whether the universities themselves should be thinking more along the lines of selectivity and concentration, unprompted by bodies like the SRC, in the light of the present stagnation of university funds, and whether postgraduate students would be better off if the doctrine of selectivity and concentration were practised more widely. If more universities are ever again set up in Britain one hopes desperately that they will not feel it

incumbent upon themselves to have, say, a geology department just because every university has to have one. There seems little doubt that the research student is better off in the long run in a department that is both large and broadly based—so that he emerges not as a diluted specialist but as a good specialist with a generalist aura about him. Interestingly, the report shows industry apparently facing in several directions over the usefulness of a PhD in telecommunications—some companies are adamant that the PhD training is irrelevant, whereas one says that "the best young members of its research staff have almost all received PhD training". Both views, however, probably crystallise the underlying frustration within companies that many good graduates do PhD courses before entering industry, and imply that it would be nice if that training created more advantages to the companies concerned. The SRC panel seems to deal sensitively with this kind of thinking.

Leaving university research aside, the panel's report is also important in that it spells out a catalogue of research that needs to be done in what has become an all-pervading aspect of modern life. At a time when broadcasting in Britain seems to be going through a rough patch, academics could well get their teeth into an examination of the pros and cons of broadcasting and cable systems for television, or take a fundamental look at the most effective way of using the frequency spectrum for radio, to name two of the panel's own examples. Then there are the possibilities opened up by the idea of integrated local telecommunications services—carrying telephone signals, for example, along with radio, television and other signals—and the desirability of refining conventional telephone systems to accommodate the special needs of groups like the old and the disabled.

The panel might well also have included a mention of the links between good telecommunications and the conservation of energy and other resources, though this is implicit in the idea of integrated local services. Even now a telephone conversation is often quicker and cheaper in energy than writing a letter, and projects like CEEFAX (which would provide instantly accessible news and other information on a domestic television set) are likely to have an impact on the present energy-intensive means of disseminating information through newspapers.

The SRC plainly thinks the universities have much to offer, and it can now only sit back and see if the appropriate response is forthcoming. □

Salk of human kindness

Armed with promises of financial support, 27 acres of prime building land donated by the citizens of San Diego and a strong conviction that science should be used for the good of man, Jonas Salk, an immunologist whose name became a household word when he developed the world's first polio vaccine, began in the late 1950s to plan a new venture. He wanted to establish a biological research centre dedicated "to contributing . . . to the health and well-being of man". The resulting Salk Institute for Biological Studies, now 11 years old, is a remarkable place. Colin Norman reports.

SET atop low cliffs overlooking the Pacific Ocean, just up the coast from the Scripps Institution of Oceanography and a stone's throw from the San Diego campus of the University of California, the institute probably ranks among the best known scientific establishments in the world. Salk's name alone is enough to ensure a good deal of publicity for the place, but it has also been pushed into the limelight through the works of one of its fellows, the late Jacob Bronowski, whose epic television series "The Ascent of Man" opened in North America this month. And, within the scientific community, the institute has already carved out a considerable reputation for itself in several areas of biomedical science.

Equally celebrated is the institute's stunning architecture. A striking concrete and glass design endowed with more than a touch of cubism, the structure is in fact so well known that the place has become something of a tourist attraction and the buildings have even been used on several occasions as a backdrop for fashion photographs. (Permission to film a battle scene in the central courtyard was, however, denied on the grounds that it would have been rather distracting for the scientists.) As well as attracting tourists and photographers, the buildings have also spawned reams of prose

in publications ranging from textbooks on modern architecture to *Time* magazine, the prize for which must surely go to the following florid description: "A spread of related buildings (conceived) to propitiate the gods of science even as the ancient Athenians built the Acropolis to keep their gods happy".

But how does the institute propitiate the gods of science in a manner different from other, less glamorous, research establishments? Salk's intention was to create an institute where research would be devoted primarily to health problems, but he also wanted to add an extra dimension of humanism to the place to ensure that the research is indeed, devoted to enhancing the well-being of man—biology with a conscience, Salk has called it.

In several respects, the institute has turned out much as its founder intended, but the grand design has altered a little over the years—"evolved is a better word", Salk insists—and there have recently been some significant changes in the way in which the institute operates. It has also run into its fair share of problems, not the least of which have been a chronic shortage of funds and, until recently, some discontentment among the younger researchers there.

Salk says that he first conceived the idea of founding a scientific institute in 1956, two years after his momentous

development of a killed polio virus vaccine. He was assisted in the planning by a number of prominent scientists, among whom the nuclear physicist Leo Szilard is said to have been influential, and his chief supporter was Basil O'Connor, the President of the National Foundation-March of Dimes (NFMD). The project began to take concrete shape in the early 1960s with the help of the architect Louis I. Kahn and financial backing from the NFMD (which also supported Salk's work on the polio vaccine), on a plot of land in the wealthy San Diego suburb of La Jolla. The first senior scientists were appointed in 1963.

The basic idea was to bring together a number of eminent scientists and give them tenure, freedom from teaching duties, a large amount of laboratory space, and it was hoped an adequate budget for their work. These so-called resident Fellows would provide overall scientific direction for the institute themselves, with the outside help of a panel of equally eminent non-resident Fellows who would meet once a year, advise on major new projects and on senior staff appointments.

The first resident Fellows reflected in large measure Salk's background in immunology and virology. Appointed in 1963 were the immunologists Melvin Cohn and Edwin Lennox, both of whom joined Salk from the Pasteur Institute, the virologist Renato Dulbecco, who moved down the coast from the California Institute of Technology (and who has since left to join the Imperial Cancer Research Fund in London, although he is still technically a resident Fellow of the Salk) and Jacob Bronowski, the mathematician, philosopher, broadcaster and humanist, who joined the Salk Institute from the British National Coal Board.

The next fellow appointed was Leslie Orgel who moved to the institute from the University of Cambridge in 1965 to continue his research into the chemical evolution of life. The Nobel Prizewinner Robert Holley came to La Jolla from Columbia University in 1968, and has since been working on the factors that control cell growth and division. And the latest senior appointment was Roger Guillemin, who moved from the Baylor College of Medicine in Houston to the Salk Institute in 1970, where he has continued his research into the control of the pituitary—work which recently led to the discovery of a new hormone produced in the hypothalamus, called somatostatin, which may be useful in the treatment of juvenile diabetes.

A common theme among those eight resident Fellows is that most of them have broad backgrounds—a factor which Salk says was deliberately sought when the appointments were being con-

sidered. Lennox, for example, was a nuclear physicist before he turned to immunology, Holley worked on nitrogen fixation and transfer RNA before he became interested in cell division, Orgel moved into prebiotic synthesis from inorganic chemistry, Bronowski started out as a mathematician, applied his skills to problems of evolution, developed a smokeless fuel, and was active in writing and broadcasting, and Salk has lately been engaged in writing on philosophy and ethics.

The non-resident Fellows, who meet in La Jolla in January each year to discuss the scientific affairs of the institute, include Nobel Prizewinners Jacques Monod, Gerald Edelman and Salvador Luria, and the President of MIT, Jerome Weisner. Although they play less of a role in the institute's affairs than they did during its early days, their input is still significant. Luria, for example, says that he often feels "more involved in decisions at the Salk than at MIT".

Until relatively recently, the scientific work of the Salk Institute was almost totally dominated by the research interests of its eight resident Fellows, each of whom heads a research group. In the early days, for example, much of the grant money flowing into the institute was channelled through the Fellows to members of their research group—a situation which led to some disenchantment on the part of younger scientists who wanted to pursue their own lines of research. Another cause of frustration was the fact that only the Fellows had tenured appointments; the other scientists were, in theory, less secure at the Salk than their colleagues were in the universities.

But a number of factors have recently altered both of those causes of disharmony, so that the Salk Institute now seems a relatively harmonious place to work in. Perhaps the most significant development has been the setting up of a number of independent research groups consisting mostly of younger scientists working in such fields as neurobiology, cancer, linguistics and reproductive biology. Their work is not tied to that of any of the Fellows, and according to one long-standing member of the institute, the result has been a great improvement in communications between the major research groups there. Another scientist put it more vividly: "a few years ago, nobody talked to anybody else; now the communication is excellent". One particular area which has recently benefited from such collaboration is that of cell division, where studies in three different laboratories at the Salk have recently converged to provide some clues to the factors which cause cells to grow and divide.

As for the question of tenure, last

year eight members of the institute were given the title of Associate Research Professor, and given conditions of tenure similar to those which pertain in the universities. For some of the younger scientists at the Salk, the fact that there is now demonstrably a career structure in the place could be an important factor in persuading them to stay there.

But the institute still has its problems. Like most centres of learning these days, it is short of funds, with the result that it has been difficult for the institute to move into major new areas of research. Another consequence is that the institute's work is now heavily concentrated in cancer research, largely because cancer money is relatively easy to come by compared with funds for other areas of science. A little over half of the institute's work is now concerned with cancer and related studies.

Salk points out, however, that since the institute is interested in "whatever seems to be in the forefront of advancing knowledge", cancer research is a natural area to be involved with, and it is also a good area for attracting bright young scientists.

The institute has also been forced recently to live much more off government funds than it used to. Last year, for example, some \$4.5 million of the \$7 million operating budget came from government grants and contracts. The rest came roughly in the form of a \$1 million grant from the National Foundation-March of Dimes, about \$1 million from other foundations, and \$0.5 million from private donations.

The financial affairs of the institute have, however, recently been placed on a firmer footing by the appointment of Frederic de Hoffmann as President and chief administrator. A nuclear physicist who worked on the Manhattan Project, de Hoffmann has, according to one Fellow of the institute, "brought a sense of financial responsibility" to the

place, and he is also credited with providing the impetus for many of the recent changes such as the establishment of more independent research groups and the extending of tenure to scientists below the rank of Fellow.

One measure of the increased financial stability is that the institute is hoping soon to raise sufficient money to begin a major new programme in neurobiology. Because plans for several large programmes had to be shelved when funding became tight in the early 1970s, some 35% of the laboratory space in the institute has never been occupied, and so the neurobiology programme, if it gets under way, will still leave the institute well short of its maximum capacity.

Another area in which there has been talk of expansion is the institute's human affairs programme. But that received a severe setback last August by the death from a heart attack of Jacob Bronowski, and it is yet to be determined how that side of the institute's activities will develop. Although Bronowski's work did not impinge much on the activities of most of the other scientists in the Salk Institute his range of interests clearly added an extra dimension to the place—a dimension which Salk says "will continue so long as I am here". A scientist closely connected with the institute suggested, however, that it has "never really managed to be a place where biology and the humanities were fused", chiefly because Bronowski's human affairs programme involved too few people. "A critical mass was never reached", he suggested, and there were consequently too few areas of overlap with the rest of the institute's members.

Be that as it may, the Salk Institute now seems to have entered a period of slow growth, paced chiefly by the availability of funds. After its first eleven years of evolution, it remains, in Luria's words, "overall, an exciting place". □

international news

THERE used to be a standing joke in Washington that whenever Mr Nixon wanted to demonstrate that his besieged Administration was in control of events, he would announce a set of new policies for dealing with the energy crisis which were mostly so ineffectual that he usually succeeded in demonstrating just the reverse.

Although the energy policy announced last week by President Ford has run into many of the criticisms that greeted Nixon's plans, and although it stands virtually no chance of being approved by Congress, it at least takes a tougher stand on some of the more controversial issues. And it will also receive much more serious consideration than some of the proposals that have gone before.

Ford's plans, announced as part of the State of the Union message, fall into three parts. During the next three years, he wants to cut 2 million barrels of oil a day from imports, chiefly by employing a few moderate conservation measures, allowing energy prices to increase, and relaxing some environmental controls on the burning of coal. For the medium term, he has proposed a number of measures to increase domestic energy supplies in order to make the United States "invulnerable to economic disruption by foreign suppliers by 1985". In the longer term, Ford reckons that the United States can "develop [its] energy technology and resources so that [it] has the ability to supply a significant share of the energy needs of the free world by the end of this century".

Few people have quarrelled with the goals, but many have taken exception to the means. In particular, Ford's conservation and environmental proposals have drawn heavy sniping from Congress, and his plans for stepping up domestic energy supplies have met with doubts that they can be achieved, mixed with criticisms because they may be environmentally destructive. All in all, the chances that they will be approved on Capitol Hill look slim.

As far as the short term proposals are concerned, Ford has announced that he will put a tariff of \$3 a barrel on imported crude oil by April this year. He has the authority to do that himself, without the approval of Congress, and so unless Congress acts to stop him it will be done. In addition, Ford wants Congress to pass legislation to allow the prices of natural gas and domestic petroleum to increase, and he has asked

Ford spells out his energy plans

by Colin Norman, Washington

Ford: three-point plan

Congress to amend the Clean Air Act to allow power stations in polluted areas to switch from oil and gas to coal. Finally, to prevent oil companies from making excessive profits from the energy crisis—as they have been doing for the past two years—Ford wants Congress to agree to legislation which will put a heavy tax on profits not ploughed back into research and development or exploration.

The need for some swift action is obvious. Although energy consumption decreased during and immediately after the Arab oil embargo, it has recently begun to increase so that the United States is now importing about 7.3 million barrels of oil a day, compared with 6.5 million barrels immediately before the embargo. If no conservation measures are taken oil imports are predicted to increase to about 8 million barrels a day by the end of 1977.

But will Ford's proposals do the trick? As far as the consumption of gasoline is concerned, there is good reason to believe that they will not. The Administration estimates that a combination of the import duty and the deregulation of the price of domestically produced petroleum will add about 10 to 12 cents on the retail price of a gallon of gasoline. In the first nine

months of 1974, however, gasoline prices jumped by about 40% in some parts of the country but consumption has been increasing during the past three months by about 300,000 gallons a day. (It did, however, drop by some 3.4% early in 1974, although some of that may have been because people had to queue for hours to get any gasoline at all.

Nevertheless, the Administration predicts that the higher prices will decrease imports of oil by 1 million barrels per day in 1975 and 1.6 million in 1977, while conversion of oil-fired power stations to coal will save about 300,000 barrels a day of oil imports by 1977.

For the medium term, Ford has quietly dropped his predecessor's oft-proclaimed goal of energy independence by 1980, and he has adopted instead the much more realistic aim of reducing oil imports to between 3 million and 5 million barrels a day by 1985—a level which, he says, will preclude economic disruption from a sudden shutoff of foreign supplies. To achieve such a goal, he has proposed a programme to bring on line within the next 10 years 200 nuclear power plants, 250 major coal mines, 150 major coal-fired power plants, 30 new oil refineries, 20 plants to produce 'synthetic' fuel from coal gasification and liquefaction and from oil shale, "many thousand" oil wells, and the insulation of 18 million homes.

All that will require Congress to approve legislation which will expedite the licensing of new nuclear power plants, allow strip mining of large amounts of coal from the western United States, provide tax credits for insulation of houses, allow the leasing of tracts of land on the outer continental shelf for oil drilling, and extend the time period in which power plants must remove sulphur emissions. In addition, Ford has asked Congress to approve an amendment to the Clean Air Act which will freeze controls on automobile exhaust emissions at essentially the levels to be imposed on 1976 car models, and he has also asked for authority to purchase facilities for a national oil storage depot capable of holding 1,300 million barrels of crude oil.

That package of proposals is likely, however, to draw opposition from Congress on a number of counts, chief of which is the inherent retreat from a number of painfully conceived environmental goals. Consider, for example,

the proposal to delay automobile emission standards. Ford has proposed that strict emission controls which were to come into effect in 1976 should be put off until 1981, in exchange for which the automobile manufacturers have promised to improve by 40% the average gasoline consumption of new American cars by 1980. But Senator Edmund S. Muskie, who heads a key subcommittee which will consider the proposals, has already denounced it because it "trades public health for fuel economy".

Muskie and a number of other observers have pointed out that fuel consumption of 1975 car models was nearly 14% better than that of 1974 models, in spite of the fact that Detroit had to meet strict pollution control standards for the later models. They therefore point out that automobile manufacturers can meet the fuel economy goal without sacrificing environmental controls. Furthermore, a committee of the National Academy of Sciences reported last year that it could see no technical reason for relaxing the standards, and that the cost of meeting them is outweighed by the benefits.

The plans for expediting the nuclear licensing programme may also draw fire from Congress because there is a small but growing number of nuclear sceptics on Capitol Hill, and the Joint

Committee on Atomic Energy, which would normally shepherd such a bill through the Congress, has been considerably weakened by the retirement and defeat of nearly a third of its members. To help head off opposition to the nuclear programme, however, Ford has proposed increasing the budget for research on nuclear safety, waste management and safeguards by \$41 million next year.

A more fundamental question raised by Ford's proposals is whether the United States has the capacity to achieve even the redefined goal of energy independence. In the past few years, according to the Administration's own figures, electricity utility companies have scrapped or postponed 60% of their plans to build nuclear power plants and 30% of those for non-nuclear plants, and this at a time when Nixon was urging all-out expansion to meet the 1980 independence deadline.

The reason was lack of capital for investment, and so Ford last week proposed a number of measures to attract investment capital to the utilities, and to allow electricity rates to increase steeply. That is a prospect which many legislators will not relish explaining to their constituents when they come up for re-election in 1976.

Furthermore, a committee of the National Academy of Engineering pro-

duced a study last year which simply tallied all the measures that would have to be taken to meet the goal of zero oil imports by 1985, the total of which was so staggering that the committee concluded that it is highly unlikely that the goal could be achieved. Although the redefined goal will be easier to meet, there is nevertheless considerable doubt that the capacity can be established in time.

For the long term, Ford has reiterated the Administration's commitment to energy research and development, and has indicated that nuclear power is expected to play a central role in the energy mix towards the end of the century, by which time he hopes that the United States will be so flush with energy that it can export some to the rest of the world. Although he was not very specific about which technologies will get preferential treatment, a background statement distributed with Ford's message at least indicates that the breeder reactor may have slipped a little in the list of priorities. It used to be the number one energy programme in the Nixon Administration, and although the statement indicates that some means must be found to eke out uranium resources, it says that "the breeder reactor is only one such supply source" under consideration. □

THE Administration's plans for promoting the development of nuclear power in the United States were sharply rapped from both sides last week. Two groups of scientists, each replete with Nobel Prizewinners, traded statements in Washington urging, on the one hand, a greater commitment to nuclear power for meeting energy demands and, on the other, criticising the Administration for putting too many of its eggs in one basket.

Although such sentiments are far from new, seldom have they been placed in starker contrast.

The pro-nuclear statement, which was largely the work of the physicist Hans Bethe, was released at a press conference the day after Ford unveiled his energy plans. Signed by 34 eminent scientists, including eleven Nobel Prizewinners, the statement began: "We, as scientists and citizens of the United States, believe that the Republic is in the most serious situation since World War II", and it goes on to deplore the fact that long range energy plans are emerging too slowly.

The statement urged much greater commitment to the use of coal and nuclear power. "We can see no reasonable alternative to an increased use of nuclear power to satisfy our energy needs", it states, while "coal is irreplaceable as the basis of new synthetic

fuels to replace oil and natural gas". The statement also insists that although conservation is desirable, large cuts in consumption can be made only at the expense of jobs.

Asked why he drafted the statement, Bethe said that he had "felt for some years that nuclear energy was not getting enough emphasis", although he said that Ford's energy proposals—which were announced after the statement was written—are a great improvement. Among those who endorsed the statement were William O. Baker, President of Bell Laboratories, Harold Brown, President of CalTech, Joshua Lederberg of Stanford University, Franklin Long of Cornell University, Edward Purcell of Harvard University, Glenn Seaborg, former chairman of the US Atomic Energy Commission (AEC), Frederick Seitz, President of Rockefeller University, Edward Teller of Lawrence Livermore Laboratory, and Richard Wilson of Harvard University.

But critics of nuclear power have also taken exception to the Administration's nuclear plans, though from a different standpoint. On the day that Bethe released his statement, Ralph Nader sent a letter to President Ford urging him to "personally review the implications of dependence on nuclear power", citing "the unique and substantial hazards associated with the

massive amounts of radioactive materials that would inevitably be created by a full scale nuclear power program". The letter was endorsed by eight eminent scientists.

Nader's letter notes that nuclear accidents could endanger "our children and their children, for generations" and states that early enthusiasm for nuclear power has "been steadily eroded as the problems of catastrophic accidents, long-term waste disposal, and the specific hazards of plutonium have been more fully appreciated". In contrast to which, Bethe's statement says that nuclear critics "lack perspective as to the feasibility of non-nuclear power sources and the gravity of the fuel crisis", and expresses "confidence that technical ingenuity and care in operation can continue to improve the safety in all phases of the nuclear power program".

Although neither statement will have much impact on the Administration's plans, they do at least testify to the wide divergence of opinion within the scientific community on nuclear safety. And a heated exchange at the press conference between the chairman, Ralph Lapp, and Daniel Ford, a spokesman for a group which has played a leading role in opposition to nuclear power, confirmed that those opinions are very firmly held.

WORD is getting about that next year's federal grants for research in Canada will be greater than they have been for some years. How much greater no one will say until the official announcement is made (possibly in February), but they will probably increase at least a little in real terms.

Since 1975 will be the year of the new federal granting structure, this may do something to restore the flagging faith of Canadian scientists in their government's interest in science—flagging chiefly because of the steady decrease in research funds available relative to costs and inflation.

At the same time, student enrolment has risen steeply. In six years, starting with 1968, the total Canadian student population increased by about 30%. But in the same period, biology enrolments alone, for example, increased almost 130%. And in eastern Canadian universities the increases were even greater—45% for total enrolment and 190% for biology. During the same period there was an increase of 70% in the number of full-time biology teachers.

But neither operating budgets nor research grants have kept pace. One chairman of a biology department reported a doubled student enrolment in five years coupled with a decline of 20% in his operating budget.

Since 1969-70, the total increase in parliamentary appropriations to the National Research Council (NRC) of Canada for research grants and graduate scholarships has been only 7%. Yet during the same period the cost of research is estimated to have risen by about 50%, and inflation in the cost of scientific equipment and materials has been even greater.

Thus the effective investment in research covered by the NRC grants has actually been reduced by more than a third. The Medical Research Council did little better.

Pronouncements by the government that reorganisation of the granting councils is going to take place this year have done little to reassure the scientists. Last February's Speech from the Throne, in which the announcements were made, "indicates only a concern for procedure and administration", said Dr J. A. Morrison, Director of McMaster University's Institute for Materials Research. "If the present trends continue, there may not be any academic research to administer within five years."

Now it looks as though the government intends to modify its policy somewhat. Late last year, the government approved a supplementary grant of \$2.5 million for the Medical Research Council. And in a House of Commons session last November, C. M. Drury, Minister of State for Science and Tech-

Canadian government ponders MOSST's mission

from David Spurgeon, Ottawa

nology and former Treasury Board President, indicated that the situation was being studied sympathetically. Given the increase in prices and inflation, he acknowledged, "it would be necessary to raise the amounts [of grants] for university research."

Another minister, Hugn Faulkner, the Secretary of State whose department is responsible for grants for the social sciences and the humanities, tried to reassure academics on the reorganisation of the granting bodies in a speech to the Association of Universities and Colleges of Canada; this is another matter that has been vexing them recently.

"No radical changes in the granting policies and practices are sought," he said. "... I can assure you that in drafting the bill, which will be tabled in the course of this session of Parliament [probably not before April or May] every possible effort is being made to take into account the fundamental concerns of the academic community."

The most effective guarantee of the acceptability and effectiveness of these councils will lie in the quality of those appointed to them, the minister said, and "the government intends to give its closest attention to this matter before making its final decisions."

Such reassurances were needed because, altogether, 1974 was not a very good year for instilling in scientists confidence in the government's approach to science policy. Part of the problem was that everybody was trying to figure out what the new Ministry of State for Science and Technology (MOSST) was up to. Conceived in controversy and born in discord (in 1971) the MOSST seemed to be suffering from an identity crisis.

The case was admirably—if rather

Drury: last-ditch effort.

critically—set out in a report published by another government creation, the Science Council of Canada, which has the independence to hire consultants, who do studies for it which it then publishes. This one was called *Knowledge, Power and Public Policy* (Science Council of Canada Background Study No. 31, Information Canada, Ottawa). Its authors were Peter Aucoin, a political scientist, and Richard D. French, a science historian.

The study examined the concept of the ministries of state, which were established with the authority of a 1970 bill to be responsible for designated policy fields not encompassed within the jurisdiction of any single existing government portfolio. The two such ministries studied were science and technology, and urban affairs.

"The ministers of state", say Aucoin and French, "would be faced with a novel task. The organisations that would serve them would not be departments in any traditional sense, but rather ministries whose initiatives would inevitably and consistently involve the responsibilities of other ministries. Fundamental to the notion of a ministry of state is the idea that the activities of research and policy analysis can provide an adequate basis for successful policy formulation and co-ordination. The logic underlying such a ministry derives from the 'knowledge-is-power' hypothesis: namely, that research, information and analysis will carry the day in Cabinet and Cabinet committees against the traditional sources of political and bureaucratic power."

They do not see the concept as a great success so far. Concerning the two ministries studied, they say: "Neither Ministry of State can be said to have had the kind of policy success that was envisaged when they were created." And concerning the MOSST: "The performance of the ministry in relation to the scientific and technological community can hardly be considered a success to date [early 1974]."

Aucoin and French conclude that "the most promising strategy for the MOSST may well be a more modest, more pragmatic, more incrementalist, and less visible role than heretofore", one with a non-threatening service posture rather than a directive one.

There are signs that the suggestion is being heeded. Some see Mr Drury and his deputy as having been sent to make a last-ditch effort to clear up the ministry's problems, in an attempt to determine whether it really can survive or not. And Drury is reported to have commented privately, "If you want to know what will happen to the MOSST, read the Aucoin-French report and use your common-sense." □

THE next move has now been made in the discussions on the desirability and safety of certain types of experiment aimed at producing microorganisms containing new combinations of genetic material. According to the Working Party set up last August by the Advisory Board for the Research Councils under the chairmanship of Lord Ashby, the potential hazards inherent in many of the new techniques for manipulating the genetic make-up of bacteria can be sufficiently minimised to allow the work to continue.

The problem was brought to the attention of the public by a group of American scientists who had pioneered these techniques. A committee of the National Academy of Science under the chairmanship of Professor Paul Berg proposed a moratorium on several lines of research: the construction of new plasmids containing combinations of virulence or drug resistance genes not found naturally, and the transfer of such plasmids into organisms in which they do not already occur naturally; and the linkage of DNA from tumour viruses to plasmids or other viral DNA. Much of the danger from these experiments stems from the fact that the bacterium most commonly used as host is the common gut bacterium *Escherichia coli*, which might be the means of disseminating the new genetic combinations amongst humans with unpredictable results.

Conventionally trained microbiologists and bacteriologists have often regarded with some horror the cavalier way in which molecular biologists and biochemists have tended to treat the organisms with which they work, and can perhaps be forgiven for regarding the current concern over bacteriological hazards with some sense of *déjà vu*. Their answer to the problems posed by possible novel organisms is that with proper precautions these bacteria can be contained in the same way that dangerous pathogens have been successfully contained in the past.

While recognising that the cases are not exactly parallel, the Working Party in its report comes down firmly in favour of the view that proper precautions can indeed reduce the risks from experiments in genetic manipulation to an acceptable level. They recommend that all those working with the new techniques should be trained in dealing with pathogenic bacteria and should have access to expert advice on the precautions necessary in any given case. All laboratories contemplating such work should be properly equipped and very hazardous experiments should only be carried out in special laboratories.

Certain simple and relatively inexpen-

sive precautions, such as no smoking, eating or drinking in the laboratory, wearing gowns and gloves which are removed before leaving and the sterilisation before disposal of all contaminated material, should suffice in most cases. More sophisticated procedures are available for dealing with material such as tumour viruses where the risks are potentially greater. There are also ingenious ways in which bacteria can be to some extent "disarmed" by muta-

Round Britain

tions which do not allow them to grow at above a certain temperature or without some rare growth factor.

Other recommendations include the epidemiological monitoring of all those working with the new techniques, special precautions to be taken when dealing with large-scale experiments and investigation into systems which might prove less hazardous than the commonly used *E. coli*-drug resistant plasmid combination.

The report should provide a timely basis for discussion at the conference called by Professor Berg and scheduled to be held next month.

● The daring young man on the flying machine is Dr Magnus Pyke, Secretary of the British Association for the Advancement of Science, currently to be seen on British television, advertising the appearance of a new partwork about science. Actually his machine amounts to nothing more than a pair of roller skates and a handful of bricks, so nobody seriously expects Pyke to fly. The aim is simply to demonstrate the principle which causes a jet to move—equal and opposite reaction stuff which

comes into play when Pyke throws the bricks in one direction and rolls off in another. The BA Secretary, who always makes entertaining radio or television, says the demo fits neatly his function as an explainer of scientific thought to a mass audience. So it's an important roll.

● The recent death in a London hospital of a patient suspected to be suffering from the virus disease Lassa fever highlights the growing problem of importing exotic and often dangerous diseases into Britain.

Ever since its discovery in Nigeria in 1969, Lassa fever has been viewed with trepidation by health workers. The four epidemics which have occurred in West Africa since 1969 have all been marked by a high death rate among hospitalised cases and by a high risk of infection by close contact, which puts nurses, doctors and relatives caring for the patients at great risk from virus-laden blood, urine and other body secretions.

There have been several cases of Lassa fever imported into Britain, the most recent being earlier this month, when a doctor returning from Kano in Nigeria, died of Lassa fever in the London Hospital for Tropical Diseases two days after his arrival in the UK. As with many tropical diseases, the main problem is a correct diagnosis, especially in Britain. Lassa fever in particular starts with a slowly mounting fever followed by headache, backache and nausea, and unless the doctor is aware that the patient has recently arrived from West Africa, where the disease is endemic, it is almost impossible to diagnose.

● GALLOPING inflation coupled with the slump in capital values of investments has finally forced the closure of one of the oldest established biomedical laboratories in Britain, the laboratories of the Lister Institute of Preventive Medicine in Chelsea Bridge Road, London.

An extra £300,000 a year at current prices would be needed to keep the laboratories in business. But at the end of last year, it was announced that it had been impossible to secure sufficient new funds to prevent the laboratories from closing in 1975.

Warning notes have been sounded over the past few years and the research effort had already been reduced to a level which the Governing Body regarded as tolerable only in the very short term. The laboratories in Chelsea Bridge Road were opened in 1898 and have been in continuous use for the 77 years of their existence. Over the years the institute has made important contributions to the understanding of infectious diseases and parasitology, as well as of basic chemistry and biochemistry.

More than just preparing

from Vera Rich, London

THE launching of the two-man spacecraft, Soyuz 17, and its link-up with the orbiting space station, Salyut 4, should not be considered simply as a preparation for the forthcoming Soyuz-Apollo project. So said Major-General Georgii Beregovoi, Head of the Cosmonaut Training Programme, at a press conference given after the successful link-up. On the contrary, he says, the joint Soviet-USA missions will merely be a part of the Soyuz programme, "a chance to broaden the range of tasks which can be solved using the Soyuz craft".

Although this comment may be interpreted as an echo of the confidence which the successful link-up has evoked in the Soviet space planners after a year notable for its setbacks, there is more to it than simply post-launch euphoria. The primary aim of the current mission, said Beregovoi, is to test out a new control and life-support system. According to the TASS data, this involves approximately normal atmospheric pressure and temperature in the cabin, representing a return to standard Soviet procedure after Soyuz

16, which with its reduced cabin pressure and increased oxygen content was a compromise with US practice.

The control system referred to is presumably the new autonomic navigation system, based on the use of ionic sensors and permitting the station to be orientated with respect to the Sun, Moon and planets in various regimes of orbital flight, and which also includes a device for orientating the spacecraft with respect to the earth in conditions of minimum illumination above the night side of the planet.

Nevertheless, even if Soyuz 17 is not a direct preparation for the Soviet-US mission, its success or otherwise must surely affect the confidence of the space planners of both nations in the outcome of the joint project. □

The Shtern case

The case of Dr Mikhail Shtern, formerly Director and Senior Consultant in the polyclinic of the Vinnitsa Provincial Endocrinological Health Centre has, during the course of pre-trial investigations and the trial itself, caused considerable reaction in the West, which has not passed unnoticed by the Soviet authorities. In the pre-trial investigations, the charges against Dr Shtern ranged from dissi-

dence to the murder of child patients. Apparently as a result of the protests, and also because it proved impossible to find witnesses to substantiate the murder charge, when the case finally came to trial the only charges Dr Shtern faced and those for which he was duly sentenced were those of "swindling" (charging for medical treatment) and "the taking of bribes".

Although these are clearly less serious charges than murder (or, in a Soviet context, dissidence), they seem intended to take Dr Shtern's case outside the competence of such organisations as Amnesty International which undertake to deal with cases of "prisoners of conscience". In the past 18 months, how every, there have been several cases of would-be emigrants to Israel facing criminal charges and, in Dr Shtern's case it was admitted on May 29, 1974 by the Procurator of the Investigations Department, V. Kravchenko that the preparation of an accusation against Shtern was connected with the desire of his family to emigrate to Israel. Accordingly, those who have been campaigning for Dr Shtern have shown no signs of being put off by the circumstances of his conviction. New letters of protest are being prepared, seeking a reversal of the verdict and sentence. □

THE Israeli Government has set up a Ministerial Committee for Science and Technology to tackle problems of research and development, and to determine whether activities in these fields are in line with the general policy of the government.

The scientific community in Israel feels that the establishment of the new committee is long overdue. Scientific and technological activities in the country have expanded extensively during the past five years; mainly because of governmental support its share in total civilian research and development and education investments was 69% in the fiscal year of 1973-74. This share increases when investments in defence research and development are included, since these are totally covered by the government.

The overall investment in research and development and higher education—both civilian and defence—reached a total sum of IL 1,500 million. There is, however, growing public criticism because of what is felt to be a lack of central policy in allocating government and public funds to achieve more direct and positive results. For instance, it is felt here that universities—which are private institutions—are supported too heavily by the state, whereas elementary and secondary schools suffer from lack of funds and teachers. It is also felt that a good deal of the

money spent on civilian research and development yield few benefits to the country in these trying days.

Israel is blessed with a 'brain influx', an inflow of professional manpower. An exceptional phenomenon for a small and developing country, this influx consists of local university graduates, of Israeli researchers who return home after working abroad for several years (mostly in the USA), and of

New Israeli science committee

from Kipai Pines, Jerusalem

scientist-immigrants from North and South America, Europe and lately from the Soviet Union.

Alas, the blessing might become a misfortune if this manpower is not used to best advantage. A central policy is needed and it is hoped that the new Ministerial Committee for Science and Technology will also tackle this problem.

The committee's tasks include: (1) ratification of the general policy of the state for the advancement of scientific research and technological development and the application of

them to meet the economic and social needs of the country; (2) deciding the goals of the state's budget in the fields of research and development, and its priorities; (3) defining inter-ministerial procedures which will assure coordination of all government operations in science and technology; (4) rectifying any changes in the organisational layout of the research carried out in government laboratories; (5) confirming appointments of Chief Scientists in state ministries; (6) confirming any other functions in the fields of science and technology which the committee will think fit.

To stimulate the committee and to give emphasis to inter-ministerial problems, it is composed of ministers whose ministries engage in scientific and technological functions: The Prime Minister (chairman), a minister without portfolio (vice-chairman), and the ministers of finance, defence, health, education and culture, agriculture, commerce and industry, interior, housing and transportation. The coordinator of this committee is the Director-General of the National Council for Research and Development, Dr Eliezer Tal.

● Professor Saadia Amiel, one of Israel's leading atomic scientists, has been appointed to the strategic planning division of the Defence Ministry, according to a report in the *Jerusalem Post*.

North American diary

from Angela Croome

THIS month off an island in Hudson's Bay and about 2,000 miles from anywhere else an American adventurer plans to bore a hole through some six feet of sea-ice and with heavy lifting equipment hoik to the surface a New Bedford whaler that sank there 100 years ago. The assumption is that the hull would remain intact during this rough-and-ready recovery but if not, Alexander Byron, the New Bedford restaurateur behind the scheme, is equally confident of cobbling it together on the spot and sailing the ship back to its Massachusetts home port. All this in the polar night with temperatures down to -22°C .

He is offering similar caesarean treatment for the remains of the two Knight expedition ships of 1719, the wrecks of which have also been found on the bottom of the Eastend harbour of Marble Island. These were a British sloop and frigate chartered by the Hudson's Bay Company through the enthusiasm of its lately retired and nonagenarian 'governor' of North American depots, Sir James Knight, who was convinced of a river of gold at the end of the equally mythical North-west passage to the Pacific. The expedition got no further than Hudson's Bay, lost both ships in a violent storm and perished lingeringly after three years cut off from the mainland on Marble Island. The Knight expedition is one of the most pitiful tales in the whole gamut of polar exploration, and there would be unique archaeological and expeditionary interest in the actual remains of this early polar voyage. Most of this evidence is bound to be lost by the recovery methods proposed at present. One can imagine the outcry there would be in Britain if a 250-year-old expedition ship and its contents were to be rudely winched from the sea bed without regard to conservation, recording or any other archaeological techniques.

Not so in Canada—although two distinct licences have to be obtained from government departments before any project may be pursued in the Northern Territories. Admiration of the old North American virtue of "can-do" still, it seems, outweighs the value put on the epic past.

● The campuses are taking the lead in concern for the energy environment in a way that one looks for in vain outside America. While British government offices have only recently introduced a 60°F heat limit, all the professors' houses I visited in the USA and Canada this winter had their temperatures set at something less than

A New Bedford whaler of the type that Alexander Byron may fish up.

60° , and had been so at least since the beginning of last winter.

Walking is becoming quite fashionable at Princeton, Harvard, McMaster, Sarah Lawrence and other suitable centres though a nasty mugging of a sociologist's wife in Cambridge recently has discouraged movement on foot after dark. Bicycles are widely replacing cars on campuses too—sometimes with rather grisly results because American academics are wedded to the idea that cycling is *sportif* and that a bicycle is not 'traffic'. The common regulations of lighting and flow direction are scarcely observed and it is a disconcerting experience indeed when driving at night to meet an oncoming cyclist, head well down, with no lights and on the wrong side of the road.

This approach contrasts strongly with that of the motorist. The reduction in traffic deaths during last winter's fuel crisis was so remarkable that a speed limit of 55 miles an hour has been adopted permanently for all roads in the USA. The amazing thing to a European is that everyone conforms, and in the most orderly and disciplined fashion. The massive overpowered machines, still gobbling gas at a rate of about 15 miles to the gallon, progress on the expressways in a well spaced and stately stream at an average $52\frac{1}{2}$ miles an hour. Driving is emphatically no longer a blood-sport in the United States—as it is (one realises anew) for Europeans, especially the British, and, indeed, for Canadians. There is no nonsense with a national speed limit or courtesy between drivers on the six lanes of the Queen Elizabeth Highway, supposedly the world's most travelled road, which connects Toronto to the industrial heartland of the United States.

● Cholesterol is the other general campus preoccupation. While women

and children tuck in as ever to butter and eggs, the middle-aged husband resolutely sticks to dietary margarine and a one-egg-a-week regime. And, of course, he 'jogs'—typically a mile a day and in appropriate dress. The whole thing is taken so earnestly, with or without medical evidence of enhanced cholesterol levels, that one wonders whether the cholesterol scare is a subtle conspiracy by Women's Lib to chastise the profligate male.

● Vasectomy—an operation only really popular in England among policemen apparently—is both widely performed and discussed. "Did I know many men who had had the operation?" Well, I do now. Perhaps this is another reflection of the leadership of the campuses in environmental concern.

● But there is a freemasonry among early morning exercisers that has much to recommend it. A Washington journalist who shares a taste for tennis rather than jogging with one of the country's most dedicated astrophysical experimenters, found himself the repository of speculation about why the scientific press neglected the amazing results emerging from the new generation of super-large radio interferometers. The 90-mile baseline proposed for this type of work when—and now if—Jodrell Bank's out-station at Meifod, Wales, were built is piffling in comparison with the power of interferometer systems using baselines which rely on telescopes continents apart. Such an arrangement is already in use synchronising telescope observations in the USA and the Soviet Union. The next stage, a Moon-Earth link-up, would give a baseline 250,000 miles long and an analytical power in proportion. Already the infrastructure of cosmic processes in undreamt-of detail is rolling off the computers on which this instrumental approach depends. □

Message to the stars

from Ian Ridpath

MANKIND'S first deliberate message to other civilisations among the stars has long since left our planetary system, leaving behind it on Earth certain rumblings about the way in which it was done. The media, both popular and scientific, outside the USA have turned such a deaf ear to this momentous event that the adjacent diagram, transmitted by the slower methods that remain conventional on Earth, may be the first detailed description of it to reach many parts of the community.

The 1,679 part message was transmitted in 169 seconds from the 1,000-foot Arecibo radio telescope in Puerto Rico. The frequency used was 2,380 MHz (wavelength 12.6 cm)—not one of the standard lines suggested for interstellar communication, but instead the top end of Arecibo's radar astronomy facility that is being used for projects such as the detailed mapping of Venus.

Writing in *Nature* for October 5, 1973, Frank Drake and Carl Sagan of Cornell University noted that the telescope's few capability would allow it to communicate with an identical instrument anywhere in the Galaxy. The Arecibo message, transmitted after a re-dedication ceremony following the resurfacing of the Arecibo arch, can only be seen as an attempt to demonstrate the truth of their proposition.

The key to the message is that it breaks down into a grid, 23 characters by 73. The diagram shows the picture that can be built up from it. Reading from top right (a tricky start) the pictogram describes in binary form the numbers one to ten as a kind of lesson to establish the language of the following message. Below this top row of numbers is a group displaying the atomic numbers of hydrogen, carbon, nitrogen, oxygen and phosphorous.

Next, the message uses this information to describe the molecular components of DNA and on lines 32 to 46 actually depicts DNA's double-helix structure. The central core is the number 4,000 million—roughly the number of characters in the genetic code.

All this adds up to a description of the chemical basis of terrestrial life: next comes a cryptic human (Ned Kelly in gumboots?) with an indication of his height to the right (14 wavelengths of the transmission) and on the left the approximate number of the human population (4,000 million again).

On the next line is a sketch of the solar system, with below it a representation of the Arecibo telescope itself, pointing downwards to a number that roughly describes its diameter.

This interstellar IQ test was devised

by members of the National Astronomy and Ionosphere Center, of which Arecibo is part. Radio astronomer Frank Drake of Cornell University, which runs Arecibo, says that the contents of the message were arrived at after exhaustive discussions, and after being 'market tested' to see how easy it was to decipher. Some people, doubtless familiar with the workings of the originators' minds, managed to unravel most of it. But a spot check in the *Nature* office revealed no intelligences (native or alien) that could decipher it. Are interstellar IQ tests culture fair?

The message was beamed at the globular cluster M13, which is 24,000 light years away. At that distance the radio telescope beam just covers the cluster's 300,000 stars. Astronomer Carl Sagan estimates that there is a one in two chance that there will be a civilisation there to receive it. The signal frequency was modulated to correct for the motion of the Earth in space, although other radio astronomers have pointed out that just such a Doppler shift on an interstellar signal would give valuable information about the orbit of the sending planet and its axial spin, as well as its size.

The single transmission of such a message cannot be regarded as a very serious attempt at interstellar communication; more likely, it will serve as an example to boost the funding chances of those who wish to listen for similar messages coming to us from other civilisations. No prior news of the Arecibo message was given, even to delegates who discussed interstellar communications at the previous month's International Astronautical Federation meeting in Amsterdam.

Yet at the 1971 International Meeting on Communication with Extraterrestrial Intelligence (CETI) the delegates concluded that such undertakings were best done "by representatives of the whole of mankind".

Drake now says that he did not consider the Arecibo message a major enough event to require international cooperation. But Tony Lawton, a member of the CETI standing committee of the International Academy of Astronautics, thinks that it has established "a very nasty precedent" and is frankly surprised that it has been done at all without prior international discussion and approval. He says that "now there is nothing to stop any nation from transmitting any signal, anywhere, to any spot it chooses. A little warning, a little consultation, would have been better."

The critics still have time to influence matters for the future. The Arecibo message is planned to be repeated when telescope time permits, although no dates have yet been chosen.

Above: the message. Below: answer?

news and views

G-wizardry at Dallas

from John Faulkner

ASTROPHYSICISTS experience biennial urges to congregate in the Texas Symposia on Relativistic Astrophysics (irreverently, Gee-whizz meetings). Recently, five hundred participants assembled in Dallas where from 16–20 December almost fifty scheduled speakers and many more in so-called workshops, summarised progress since the last meeting (*Nature*, **241**, 169; 1973). Necessarily incomplete impressions follow.

Cosmology opened the proceedings. Reeves (SEP-CEN, Saclay), noting the embarrassingly large interstellar deuterium abundance, remarked "Anybody who wants to believe in the big bang producing a closed universe had better invent a way of making deuterium; and that's not easy, I can tell you". Colgate (University of New Mexico) suggested supernova shock waves as a site, but the general impression of a severe restraint remained.

Gunn echoed this theme in his State of the Universe message (traditionally reserved for Caltech and its satellites). Gunn and colleagues have assembled many arguments (stellar, nuclear, inferred densities, and so on) pointing to an open Universe (see *Astrophys. J.*, **194**, 543; 1974). He and Oke, with seventeen new redshift-magnitude points for $z > 0.25$, produced a "classical test" which disconcerted many. Tinsley (University of Texas) later presented spectroscopic evidence for giant-star dominated ellipticals. The implied evolutionary dimming necessitates reductions in observed values of the Sandage variable q_0 by 1 to 1.5 or more. Thus emerged a large, negative value for the true q_0 ; alternatively, a large positive value for Einstein's disinherited Λ , the cosmological constant. When Fowler (Caltech) arose to demand if this were so, Gunn retreated to the sanctuary of probable errors. Perhaps cosmologists should always state "These are the opinions upon which I shall base my facts".

Ostriker (Princeton University) supported the density estimates when discussing halos of galaxies. Galactic disk stability requires a massive halo. Elsewhere, masses from mass-luminosity ratios increase with scale up to the 'virial masses' of clusters. New data obtained with Spinrad reveal extended red halos around edge-on spiral galaxies; the now respectable virial masses still fail to close the universe.

The observations of neutral currents in weak interactions have had dramatic effects on supernova theory. Schramm (University of Chicago) summarised implications for collapsing iron-nickel core models (descending from the work of Fowler and Hoyle). Freedman's suggestion that neutrino scattering cross-sections will scale as the square of atomic number may be the key permitting central collapse to neutron stars of black holes, while producing mantle ejection. Arnett (University of Illinois) has followed evolution from well understood helium burning to the hydrodynamic phase of neutron-star formation. Wilson (Lawrence Livermore Laboratory) and Bruenn (University of Florida) found shock waves in collapse calculations. Whether black hole formation or nucleosynthetic eruption would ensue was unresolved. Later Weinberg (Harvard University) presented a virtuoso account of the furore in physics and astrophysical consequences. Neutral currents, charmonium and a possible unification of strong, weak and gravitational forces at large energies were tantalisingly dangled before a mesmerised audience.

The mysterious gamma-ray bursts were discussed by Strong (Los Alamos) and Cline (Goddard). In one doubly observed event Vela detectors caught only the tail-end; earlier onset data should thus be regarded with caution. Ruderman (Columbia University) regaled listeners with a scintillating review of the flood of unconstrained theories, more numerous than the events themselves, involving black holes, neutron stars, antimatter, white holes, novae, ablating relativistic dust grains. "Nothing is too wonderful to be true, but there is not yet much else to support such a host of clever inventions."

Developments in relativity theory were reviewed by Ellis (University of Cape Town) and Trautman (Warsaw). Ellis emphasised that Bianchi (spatially homogeneous but anisotropic) cosmologies can have very different singularity

properties from those usually considered. Matter can originate in spatially inhomogeneous regions, cross prediction horizons, and end up in spatially homogeneous regions. Some charmingly named universes (for example, "Whimper-bang-whimper") await discovery; it was noted with evident relish that the steady state begins not with a bang but a whimper. Teukolsky (Cornell University) reviewed black hole perturbations, where Chandrasekhar has developed some unifying formalism. Practical gravitational radiation was almost conspicuous by its absence (a noted observational characteristic?). The anti-Weber climate (*Nature*, **250**, 287; 1973) has had curious backlash effects on other work involving gravitational radiation. Spectroscopy of HZ29 showing evidence for the predicted mass transfer was first dismissed by an organiser as the work of self-evident cranks. Hawking (University of Cambridge) penitently confessed that black holes were white hot, emitting through quantum effects, radiation which makes small holes ($\lesssim 4 \times 10^{14}$ g) evaporate in less than the age of the Universe.

X-ray day dawned. A promise by Giacconi (Harvard University) that the meeting would now become interesting, was amply fulfilled after his talk when Pounds (University of Leicester) showed Cen X-3 data from the UK-5 satellite with a strong dip at phase 0.62 in each binary period. This was regarded as excellent support for the extended Pringle wake model which Giacconi had presented. The day ended with mad scrambles between two simultaneous X-ray workshops involving no fewer than 38 speakers.

Strittmatter (University of Arizona) was permitted 25 minutes to cover QSOs (how are the mighty red shifted!). After suggesting that much of the effort on BL Lac had been misdirected, he discussed the increasing evidence for multiple absorption redshifts and line-locking (for example CIV in 3C191) agreeing with Scargle's predictions. A new $z=3.2$ QSO was announced which, like OH471, appears neutral or reddish. It reopens the question of selection effects once more and emphasises the importance of working systematically through Hazard's suitcase-full of unbiased accurate positions. Small scale radio structure was described by Cohen (Caltech). Apparent linear 'expansion'

velocities up to $\sim 10c$ are seen, and in 3C273 three independently varying components simulating motion can be ruled out. Four or more components are required for the 'theatre marquee' effect to work, but the existence of 'expansions' only is a puzzle.

The organisers, perhaps with the misguided intent of reserving the finest vintages till last, arranged three of the most important papers for the final chaotic afternoon. The Brans-Dicke theory received two almost mortal blows. Hill (University of Arizona) finds the solar oblateness at a time when confusing excess brightness is absent to be lower than Dicke's value by more than an order of magnitude. It agrees with expectations for a uniformly rotating Sun to within 25%. Consequently, Mercury's perihelion shift has a negligible contribution from a quadrupole gravitational field and supports Einstein over Brans-Dicke.

One fascinating by-product emerged: old Sol is breathing (pulsating seems too strong a term) in a number of modes including the gravest, ~ 54 min (geophysicists note!). Fomalont (NRAO, Green Bank) reported results of the microwave radiation bending from three QSOs with angular positions close to the Sun's path in April. The result, 1.015 ± 0.011 times the Einstein prediction, is not consistent with a scalar coupling constant $\lesssim 23$. Finally, Taylor (MIT) announced that the binary pulsar 1913+16 is indeed showing apsidal motion of 4.0 ± 1.5 degree yr^{-1} , consistent with general relativity and suggesting two compact components of ~ 1.3 solar masses each.

The meeting was a great success, if at times in spite of the arrangements by the 19-strong organising committee. I thank those many speakers who, guided no doubt by self-preservation, provided summaries of their talks.

least some of this material would seem confirmed the dating is not quite so clear. The geological sequence in the Hadar area seems well worked out but the fact that this fossil material was not found *in situ* but was scattered over a considerable area of the surface has led the researchers to express some doubt over the exact position of its original location within the sequence. Thus the "niveau à hominidés" designation in the geological column is followed by a query (?).

In October, 1974 further hominid remains were reported from the Hadar area. These remains, consisting of four jaw fragments, include a complete maxillary arcade with only the incisors and one canine missing. The first report of this material, at a press conference in Addis Ababa on October 25 (see *The Times*, page 6; October 26, 1974), included the following statement:

"These specimens clearly exhibit traits which must be considered as indicative of the genus *Homo*. Taken together, they represent the most complete remains of this genus from anywhere in the world at a very ancient time.

"All previous theories of the origin of the lineage which leads to modern man must now be totally revised. We must throw out many theories and consider the possibility that man's origins go back to well over four million years."

These are rather strong statements and may be examined on several levels.

First, although the reported potassium/argon date of 3.01 ± 0.25 Myr for a basalt in the Hadar area may well be valid this fossil material, as with the 1973 specimens, was not recovered *in situ* but was collected on the surface. Thus, the specimens' relationship to the dated level cannot be known with complete certainty. In an area such as the Awash ephemeral stream activity can move material over considerable distances and the absolute dating of surface finds must be viewed with some scepticism. Second, no morphological or metrical data have been presented so that the attribution of this material to the genus *Homo* cannot be fully evaluated. It should be pointed out, however, that the available photographs show certain features of the canines, premolars and molars which may not be entirely consistent with current definitions of that genus. Third, the statement that "all previous theories" of hominine origins must now be revised in the light of this material is simply untrue. The results of earlier field work at East Rudolf, based on material found *in situ* and in a well-dated context, have already supported an early origin of the genus *Homo*.

The final point is not, however, the

Ethiopian fossil hominids

from a Correspondent

WITHIN the last decade and a half field work in east Africa has had an extremely important impact on all aspects of early man studies. The initial impetus for east African field studies came of course from Olduvai Gorge but subsequently successful field programmes at East Rudolf in northern Kenya and in the Omo River area of southern Ethiopia have been no less important and productive. In late 1973 a new area was added to the east African inventory of fossil man sites. This new area on the Hadar River, a tributary of the Awash River, in eastern Ethiopia has produced, to date, a total of nine fossil hominid specimens.

Geological and palaeontological studies in Plio-Pleistocene deposits in this area have been in progress since 1967. These studies have resulted in a brief report (Taieb, Coppens, Johanson, and Kalb, *C.r. hebd. Séanc. Acad. Sci. Paris*, 275, August 16, 1972) of geological sequences and palaeontological remains from several sites in the Awash area. Formations at Haoua-Lédi and at Leadu have been closely correlated, on the basis of faunal remains, with deposits in the Omo River valley dated to between 2-3 Myr. Deposits at Hadar may be a little older and have been faunally correlated with the lower levels at Omo, perhaps, in absolute terms, at about 4 Myr. This latter region yielded, in late 1973, five hominid fragments: an associated right distal femur and proximal tibia, proximal left and right femora and a left

temporal bone.

A full description of this material has not yet been published but a brief report (Taieb, Johanson, Coppens, Bonafille and Kalb, *C.r. hebd. Séanc. Acad. Sci. Paris*, 279; August 26, 1974) mentions that the femoral neck is flattened anteroposteriorly and is oval in section; the distal femur, said to be "très humaine", has an elongated and flattened external condyle and a deep intertrochanteric fossa. The authors, in stressing the very small size of this post-cranial material, conclude that the height of this individual from Hadar was less than that postulated for one of the individuals from Sterkfontein. Most estimates of the height of STS 14, for example, based on reconstructed femoral length, do not exceed $4\frac{1}{2}$ foot. Perhaps the most interesting and significant feature of the distal femoral fragment is not mentioned in the text but is apparent from the accompanying photograph. It seems clear that the natural anatomical orientation of this femur would include a relatively high degree of shaft obliquity. This angulation, which would permit the knees to approximate the mid-line during upright stance, is an important hominid characteristic and distinguishes the femora of this group from those of other primates. Although this material was not formally attributed to any taxa the morphology of the temporal bone, which is highly pneumatized, was said to resemble that of the robust australopithecines.

Although the hominid nature of at

ultimate or intrinsic scientific value of these fossils; the data are at present inadequate to make such an evaluation. The point is that questions of taxonomic attribution, phylogenetic position and, ultimately, scientific importance must follow upon careful comparative studies and complete anatomical and metrical evaluation. Such a reversal of priorities, with its consequent and inevitable de-emphasis on necessary laboratory procedures is completely inconsistent with current scientific method and theory.

Stagger to deceive

by David Davies

THE problem of detecting and identifying underground nuclear weapons tests has been around for nearly twenty years. In 1958 there were high hopes that seismic techniques would prove adequate to monitor tests down to a few kilotons without any territorial intrusion. A year later these hopes were dashed when the big-hole theory was wheeled out by the American weapons laboratories—fire an explosion in large enough a cavity and its seismic signal is almost negligible. In the early sixties hopes rose and fell as the Americans, British and Russians played, inconclusively, with numbers of on-site inspections and black boxes. In the late sixties hopes began to rise as seismic methods improved and a new technique was developed based on the relative excitation of surface and body waves. In the early seventies hopes rose to a peak when there was talk on an underground test ban but there was widespread disillusion when the nature of the ban (on explosions above 150 kilotons from a date in 1976) became clear.

Now a new problem emerges. In this week's *Nature* (page 242) Kolar and Pruvost report for the first time in the open literature on techniques that could be adapted by a country wishing to evade a strict ban.

It has been widely accepted for many years that a test fired while the Earth was ringing from a really major earthquake (of the sort that occurs only once or twice a year) would be impossible to detect. This presents a rather risky prospect to the determined evader; a more measured scenario in which the evader fired at a time of his own choosing would obviously be more desirable. Yet to do this some way had to be found to increase the excitation of surface waves relative to body waves. This could be done, argue Kolar and Pruvost, by firing a multiplicity of shots, one of which would be the device under test.

The dots are the locations of presumed 'Plowshare' explosions. The triangles are Soviet test sites.

The relative excitation of surface and body waves is not actually changed by this technique, but since the techniques for measuring the excitations are relatively crude (necessarily; signal-to-noise ratio is frequently no greater than unity) it is possible to deceive the measuring process. The dominant period of a body wave is 1 second and the rules for determining excitation specify a measuring interval of three or four seconds so the apparent magnitude from a string of explosions over many seconds is of necessity low. On the other hand surface waves have a dominant period of 20 seconds, so provided the time delay from first to last explosion is kept smaller than about 10 seconds, all surface waves add in phase. Thus the apparent enhancement.

Many other precautions will have to be taken to avoid satellite and ground monitoring, but Kolar and Pruvost believe that these can be satisfied and thus that there will be serious doubt if not complete misreading in the monitoring country.

Should such ideas for deception be surfaced, revealing a mistrust of Soviet intentions? Most certainly; they have been around in the grey area between secrecy and openness for several years, and it is now necessary to take them seriously so that in any future debate on test-ban technology there will be no surprises. It will not escape the reader that the authors work for a laboratory charged with research into nuclear weapons and therefore presumably with a certain interest in forestalling any total ban on weapons testing. But no

doubt many seismologists elsewhere with a different point of view will now try to crack this new problem.

● In a related field, the figure shows the enormous extent of Soviet 'Plowshare' nuclear explosive activity. Each point represents an event reported in the open seismic listings which can reasonably be taken to be an explosion for some peaceful purpose. Yields vary from a kiloton or less to more than 100 kilotons, and the sparse literature from the Soviet Union suggests uses ranging from canal-building to oil field engineering.

Sizing the RNA tumour virus genome

from Benjamin Lewin

WHEN RNA is extracted from the C-type RNA tumour viruses, the major components sediment at 60–70S and 4–5S. After denaturation by heating or by treatment with DMSO, 60–70S RNA sediments in neutral gradients at 30–40S. The apparent $10\text{--}12 \times 10^6$ daltons of the 60–70S RNA thus seem to comprise subunits of about 3×10^6 daltons; given the uncertainty inherent in this determination of molecular weights, there might be two, three, or four subunits in the 60–70S complex. A question that has remained unaltered for some time is whether the subunits in a virion all are identical (so the genome would be polyploid) or whether they carry different sequences (giving a haploid genome). The genetic

information contained in a single subunit would be sufficient to code only for about 300,000 daltons of protein, which compares with the total weight of known viral proteins of about 3,650,000 daltons.

The presence of two types of subunit in 30–40S preparations of Rous sarcoma virus (RSV) RNA was first reported by Duesberg and Vogt (*Proc. natn. Acad. Sci. U.S.A.*, **67**, 1673–1680; 1970) when they electrophoresed the RNA on gels; these are the more slowly migrating (larger) *a* subunit and the smaller *b* subunit. The size of the class *a* subunits is in the range $2.4\text{--}3.4 \times 10^6$ daltons and that of the *b* subunits is about $2.2\text{--}2.9 \times 10^6$ daltons (Duesberg and Vogt; *J. Virol.*, **12**, 595–599; 1973). But Martin and Duesberg (*Virology*, **47**, 494–497; 1972) then showed that the 60–70S RNA extracted from cloned RSV particles derived from clonal populations of infected cells carry only the *a* subunit. In a further report, Duesberg and Vogt (*Virology*, **54**, 207–219; 1973) showed that the *a* subunit of cloned Schmidt–Ruppin strain of RSV is slightly larger than the *a* subunit of the cloned Prague RSV strain.

Different (noncloned) strains of avian sarcoma virus have different ratios of *a/b* subunits. Avian leukaemia virus particles, however, contain only *b* subunits. Since the sarcoma virus can transform chick fibroblasts whereas the leukaemia virus is unable to do so, this observation led to the concept that the *a* subunit may carry information necessary to accomplish transformation and that this sequence is missing from the leukaemia virus genome. Consistent with this idea was the observation of Duesberg and Vogt that transformation-defective variants of avian sarcoma virus all possess only the class *b* size of subunit. The derivation of *b* subunits from *a* subunits might therefore be explained by the occurrence of a deletion in the *a* subunit which removes information essential for transformation. If all the subunits in either size class are identical, then a single event would be sufficient to generate the defective viruses; but if the subunits represent different sequences, presumably a deletion would have to take place in each type of molecule in order to generate the size change between sarcoma and leukaemia virus.

Two approaches have been taken to determine the complexity of the RNA genomes and these have yielded contradictory results. Chemical analysis suggests a polyploid structure for the avian RNA virus genome. After digesting the RNA of the Schmidt–Ruppin strain of Rous sarcoma virus with T1 ribonuclease and separating the oligonucleotides on two-dimensional gels, Billeter, Parsons and Coffin (*Proc.*

A hundred years ago

THE ZODIACAL LIGHT.—On the evening of Sunday last, the 24th inst., a surprisingly bright display of this as yet problematical phenomenon was exhibited. There was a repetition on the following evening, but in a less favourable sky. The light had the usual yellowish or pale lemon tinge of the more notable exhibitions in these latitudes. The axis of the light appeared to pass λ Piscium, and the vaguely-defined apex was situate somewhere about 19 Arietis, but it was not possible to locate it with anything like precision. The light was broad and of a deeper, perhaps, ruddy tint near the horizon. The display to which we have adverted, excelled in brightness any that has been witnessed in the neighbourhood of London for many years. It appears very probable that opportunities for favourable application of the spectroscope may be afforded in the dark evenings of the present and following months.

From *Nature*, **11**, 249, January 28, 1874

natn. Acad. Sci. U.S.A., **71**, 3560–3564; 1974) obtained roughly twice the number of spots generated by 28S rRNA. By determining the molar yield of 11 of these spots, they were able to suggest a complexity for the viral genome of about $3.4 \pm 0.9 \times 10^6$ daltons. A similar estimate was made by Quade, Smith and Nichols (*Virology*, **61**, 287–291; 1974) for the RNA of the Prague strain of RSV (3.3×10^6 daltons). These estimates would suggest that the genome is polyploid, since the sequence complexity of the viral RNA is about the length of a single 30–40S subunit molecule.

That *b* subunits are derived by a deletion of *a* subunits is suggested by the chemical and hybridisation analyses reported by Lai, Duesberg, Horst and Vogt (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 2266–2270; 1973). Comparing the T1 ribonuclease digests of the RNAs of avian sarcoma viruses and transformation-defective derivatives showed that all the large spots of the *b* subunit are found in the digest of the *a* subunit; but the *a* molecules contain one or two additional spots not found in the *b* digest. The labelled cDNA prepared from the *a* subunit hybridises with about 70% of the *a* RNA when saturation is reached; it hybridises with 60–65% of the *b* RNA, a result which would be consistent with the omission from the *b* RNA of a sequence present in the *a* RNA. Neiman *et al.* (*J. Virol.*, **13**, 837–846; 1974) have compared the

RNA genome of the Prague strain of RSV with a spontaneous transformation-defective mutant derived from it by hybridising these viral RNAs with excess chicken DNA of normal embryos and sarcomas. The transformation-defective strain seems to lack a sequence present in the parent sarcoma virus.

Hybridisation experiments have been used also to measure the complexity of the 60–70S RNA of RSV. When labelled cDNA prepared from the viral genome is annealed with an excess of RNA, the reaction rate depends upon the complexity of the RNA. Taylor *et al.* (*J. molec. Biol.*, **84**, 217–221; 1974) reported a sequence complexity of 9.3×10^6 daltons, which corresponds to about three different subunits if each subunit is about 3×10^6 daltons. This clearly suggests a haploid genome. No reconciliation between the chemical and hybridisation analyses is at present apparent.

What is responsible for maintaining the association of subunits in the 60–70S complex? The denaturation maps recently constructed by Mangel, Delius and Duesberg (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 4541–4545; 1974) suggest that hydrogen bonding at several locations may be implicated. The T4 gene 32-protein binds cooperatively to single stranded nucleic acid and (mildly) denatures both 60–70S and 30–40S preparations. The molecules treated with 32-protein can then be visualised by electron microscopy. In the presence of 32-protein, 30–40S RNA is linear, appears fully coated with protein (thus losing the extensive secondary structure seen in the absence of 32-protein), and has a maximum length (some molecules are shorter, presumably due to degradation) of 2.75×10^6 daltons. The complex of 32-protein with 60–70S RNA consists of several linear molecules held together at different sites, with four to eight free ends per complex. Most of the RNA is coated with protein. The average length is 6×10^6 daltons, which would suggest that the complex includes only two subunits.

Manganese can grow rapidly

from Peter J. Smith

FERROMANGANESE nodules and crusts typically grow on the ocean floor at rates of 0.1–1.0 cm per million years and have Fe/Mn ratios of 0.5–2.0. But Scott *et al.* (*Geophys. Res. Lett.*, **1**, 355; 1974) now report that they have found a manganese oxide (MnO₂) crust with a much higher growth rate, an abnormally low iron concentration and unusual trace element characteristics. The newly discovered crust is thus

atypical but apart from demonstrating just how fast manganese can accumulate under the right circumstances, it also appears to be indicative of hydrothermal processes along active ridge crests as recently proposed in more general terms by Lister (*Eos*, **55**, 740; 1974) and others.

The crust sample in question, which is a 4.2 cm thick deposit of birnessite with a trace of todorokite, was dredged from the median valley of the mid-Atlantic ridge about 5 km from the ridge axis at 26° N. The first hint of its anomalous nature came from a radiochemical analysis of uranium series isotopes. Deep sea manganese deposits usually contain quantities of ^{230}Th and ^{231}Pa far in excess of those required for equilibrium with the parent uranium isotopes, indicating that thorium and protactinium have been taken up from the sea water during the process of manganese accumulation. The decay of these excess isotopes may then be used to determine the rate at which the manganese was produced. But the sample analysed by Scott and her colleagues turned out to be depleted in ^{230}Th and ^{231}Pa ; the manganese accumulation rate had therefore to be measured from the growth of the isotopes towards equilibrium with their uranium parents.

The rates thus determined were, respectively, 13.0 and 25.0 cm per million years, which are held to be in "reasonably good agreement" but which compare with accumulation rates of only 0.1–0.5 cm per million years for nearby samples of 'normal' manganese. This disparity explains in part the unusual trace element composition of the Scott sample, for the concentrations of trace metals removed from sea water are generally the lower the more rapidly the manganese grows. Once the accumulation rate had been determined, therefore, the low observed concentrations of Cu, Ni and Co were hardly unexpected. However, as Ku and Glasby (*Geochim. Cosmochim. Acta*, **36**, 699; 1972) noted, this phenomenon does not apply to uranium, presumably because uranium is incorporated into the manganese in a different way.

Low trace metal concentrations, rapid growth rates and high degrees of fractionation of Mn from Fe are characteristic of both hydrothermal deposits and deposits remobilised from reduced sediments. But what makes a hydrothermal origin the more likely for the Scott sample is the fact that the Mu/Fe ratios of 360–3,600 (the Fe content is as low as 0.01% in places) are much higher than those found in diagenetic continental margin nodules. Other evidence supports the same view, but is more circumstantial. For example, bottom photographs show that the site from which the Scott sample

was dredged is essentially sediment-free; thermal measurements indicate a sharp 0.14° C increase in bottom water temperature over the site; and there is a local magnetic low which could reflect hydrothermal alteration of magnetic minerals in the pillow lavas. Taking all this evidence together, Scott *et al.* conclude that the MnO_2 crust was deposited by a hydrothermal spring in the mid-Atlantic ridge's median valley.

Non-coding regions of messenger RNA

from Pamela Hamlyn

ALL purified messenger RNAs isolated so far have been shown to contain considerably more nucleotides than are required to code for their particular protein. Interest in these untranslated sequences has been centred round the possibility that they may be the site of interactions related to translational control of protein synthesis—a mechanism for which there is much circumstantial but little direct evidence. Part of this non-coding region is accounted for by the poly(A) sequence found in most eukaryotic mRNAs. Despite intensive research, the results of which have often been summarised in these pages, the function of this sequence remains obscure. Current research has shown that the poly(A) region becomes shorter as the messenger 'ages', suggesting that the length of the poly(A) region provides information about the number of rounds of translation possible before degradation of the messenger.

With these ideas in mind, Jeffrey and Brawerman (*Biochemistry*, **13**, 4633; 1974) compared the length of the poly(A) region in messengers from rapidly dividing undifferentiated cells (mouse sarcoma) with globin mRNA from rabbit reticulocytes—highly differentiated cells which do not divide. They confirmed that the poly(A) region becomes shorter with age but suggest that a terminal size is reached. Digestion of polysomes with ribonuclease yields poly(A)–protein complexes, and the authors were able to show that in mouse sarcoma these complexes become smaller and more heterogeneous with time, whereas poly(A)–protein complexes from polysomes synthesising rabbit globin are much more homogeneous. Unfortunately, these studies provide little new information, and consequently the authors have not been able to further elucidate the role of poly(A).

Results of research into the non-poly(A), non-coding regions of messenger RNAs are limited and seemingly contradictory. Nichols and Eiden (*Biochemistry*, **13**, 4629; 1974) have

reasoned that sequences next to the poly(A) region of mRNA might be recognition sites for poly(A) synthetases or else represent termination signals for transcription by RNA polymerase (poly(A) is added post-transcriptionally). They speculate that this would result in a region of homology in the sequences next to poly(A) throughout a population of messenger RNAs.

To investigate this, Nichols and Eiden have prepared ^{32}P -labelled polyosomal RNA from L cells, then digested it with RNase T_1 (an enzyme specific for guanylate residues) and, using poly(U) affinity chromatography, have isolated fragments which contain poly(A) and a few bases at their 5' ends. Sequencing of these bases showed that there was no particular sequence common to all (or even a large proportion) of the messenger RNAs, although more than 50% of the total mRNA molecules contained a single pyrimidine residue next to the poly(A). The authors conclude that there is no recognition site common to all mRNAs in terms of nucleotide sequence.

Web of immature *Eustala* (?) sp. from a forest on the Pacific coast of Columbia. W. G. Eberhard (*J. nat. Hist.*, **9**, 93–106; 1975) describes the construction of this web and an even more elongated one made by *Scoloderus* sp., also in Columbia. Both webs bear a remarkable resemblance to a ladder-like web made by a New Guinean araneid spider and described by Robinson and Robinson (*J. nat. Hist.*, **6**, 687–694; 1972).

Proudfoot and Brownlee (*Nature*, **252**, 361; 1974) have sequenced the 3' end of purified rabbit β -globin mRNA next to the poly(A) region and compared it to the sequence of bases in the same position in mouse immunoglobulin light chain mRNA (Milstein *et al.*, *Nature*, **252**, 354; 1974). They did not sequence the RNA directly but transcribed it into DNA using *E. coli* DNA polymerase I and deoxytriphosphates, one of which was labelled with ^{32}P .

Comparison of the two sequenced regions of each messenger showed that two sequences (7 and 4 bases long) were common to both messengers. As well as this sequence homology Proudfoot and Brownlee suggest that structural homology exists since both the light chain and globin 3' ends can be drawn with loops which are identically positioned and almost the same size in the two mRNAs. Most of the homologous sequence is probably in the unpaired region.

The apparent contradiction between these authors' results and those of Nichols and Eiden will probably disappear as the sequences of the 3' ends of more messengers become available.

Classical relativity in an up-to-date context

from W. H. McCrea

THERE has recently appeared a substantial paper by F. Salzman "Gravitational Field of a Freely Moving Mass" (*Il Nuovo Cimento*, **24B**, 157-188; 1974); the treatment is intended to be that of standard general relativity, howbeit with emphasis on the dynamical rather than the geometrical point of view, and the application is mainly to the case of a Schwarzschild mass. In days when there is so much interest in the gravitational and dynamical properties of black holes, such a study of intimately related problems would be expected to be particularly timely and significant. Indeed, the surprising thing is that the problems have not long ago been fully investigated. Nevertheless, while the paper is of much interest in an exploratory way, it seems that definitive results are scarcely yet achieved.

Some of the immediate background theory is quoted from the well-known books by C. Møller and by L. D. Landau and E. M. Lifshitz, and some generally relevant ideas from the writings of F. A. E. Pirani and S. Weinberg. But the central exercise of the work seems not to have been attempted before: it is to study the consequences of as nearly as possible applying a Lorentz transformation to the Schwarzschild exterior solution, seeking

Laser tuning

from John Walker

MOST lasers have the disadvantage of operating at only a few fixed wavelengths. Dye lasers on the other hand can now be tuned over the whole visible spectrum by selecting appropriate dyes. Fine tuning is accomplished by a variety of techniques, one of which involves birefringent crystals. A recent paper (Tang and Telle, *Applied Physics Letters*, **24**, 85; 1974) reports the observation of very large tuning rates using birefringence in ammonium dihydrogen phosphate (ADP).

Earlier work needed high gain pulsed dye lasers and used rather complicated tuning elements including intracavity polarisers and gratings. Tang and Telle employed a less powerful CW dye laser, and only a single z-cut electro-optic crystal of ADP. When the z axis was parallel to the direction of propagation of the light a voltage applied across the x direction had no effect on the laser wavelength, as symmetry considerations would predict. But if the crystal were misaligned by only one degree the wavelength then unexpectedly became a very sensitive function of voltage. Tuning rates of up to $60 \text{ \AA} \text{ kV}^{-1}$ were achieved, and they could be varied by changing the misalignment angle. Coarse tuning could be effected by rotating the ADP crystal. The precise explanation of the tuning effect is not known, but it seems to depend on having a crystal with very low residual birefringence in the absence of an electric field.

In any case, the method seems to be simple and useful, as Tang and Telle demonstrate in a second paper (*J. Appl. Phys.* **45**, 4503; 1974). Here they claim the first application of a laser to modulation spectroscopy, a technique which previously needed conventional light sources and spectrometers. The principle of modulation spectroscopy is quite simple. The spectrometer (or in this case laser) wavelength is caused to oscillate rapidly over a range of a few Ångströms. Using suitable electronics a signal corresponding to the first derivative of the absorption spectrum can then be extracted from the transmitted light. In practice this means that relatively weak spectral features are amplified and made visible. Tang and Telle studied the room temperature absorption spectrum of Nd^{3+} ions in a YAG crystal. They were able to resolve features which are normally seen only at liquid helium temperatures, and also detected some weak lines which are not usually seen at all.

The claimed advantages of the laser system over conventional modulation spectrometers are greater sensitivity because of the intensity of the laser light, and much better resolution. As a straightforward tunable laser the line width can be reduced to less than a tenth of an Ångström. The voltage tunability ensures very fine and reproducible wavelength selection. This versatile tuning system will undoubtedly find many applications.

thuswise to obtain a metric that might be interpreted as that of a mass in free (unaccelerated) motion. The procedure is to express the Schwarzschild solution in terms of the usual time coordinate and Cartesian-like spatial coordinates, and simply to apply a Lorentz transformation to these. Since the space-time tends to that of special relativity at large distances from the mass, the transformation has asymptotically its usual significance. The spatial coordinate system is not unique, but Salzman seeks to treat the passage from one to another admissible system as being analogous to a gauge transformation in electromagnetism. The two cases he treats in detail are "Schwarzschild coordinates" and "isotropic coordinates".

Except asymptotically, the transformation has none of the precise significance of the Lorentz transformation in special relativity. Of course, it may be qualitatively suggestive. One feature Salzman discusses that at first sight offers intri-

guing possibilities is a generalised Schwarzschild surface defined by the vanishing of the leading component (coefficient of the dr^2 term) of the metric tensor. In the coordinates used, however, this tensor is not in diagonal form, and so the vanishing of this component does not in general denote a singularity and therefore need not have any particular physical significance.

As regards the behaviour of a test particle in the field of a freely moving Schwarzschild mass, all the physical properties are derivable using any admissible coordinate system whatever. Since one is interested in only the relative motion of the particle and the mass, by far the most convenient system is the original Schwarzschild one where the metric takes the familiar form:

$$ds^2 = (1 - 2M/r) dt^2 - (1 - 2M/r)^{-1} dr^2 - r^2 d\Theta^2 - r^2 \sin^2 \Theta d\Phi^2$$

with $c = G = 1$.

One relevant matter is the case of

a test particle of proper mass m_0 moving radially inwards. It is easy to show that the local velocity v along the trajectory is related to the velocity V at infinity by $(1-v^2)/(1-V^2) = (1-2M/r)$. The local rate of change of momentum is then found to be $m_0 M(1-v^2)^{-1/2} r^{-2} (1-2M/r)^{-1/2}$ which may be interpreted as the gravitational attraction. This agrees with the classical value in the appropriate limit. One may interpret $M(1-v^2)^{-1/2}$ as the relative mass of the body as seen by the infalling test particle. The fact that this plays the part of the gravitational mass is one of the results got in a different way by Salzman. In most applications $2M/r \ll 1$, and we may think of r as nearly enough the classical distance. But the presence of the factor $(1-2M/r)^{-1/2}$ does recall the role of the Schwarzschild surface. So as far as this simple case is concerned, it checks that there is no change in the absolute position of this surface as it affects a moving test particle. Naturally, an observer on that particle may describe the surface in various ways depending upon what observations he makes of events in its vicinity.

The simple case might suggest that there is never any need to treat a Schwarzschild mass save with the aid of a standard description of the metric. But this is obviously not the case if we have to treat the interaction of two such masses. And this is where Salzman's work may provide a valuable start. In the first place, it supplies at any rate an approximation to the required field. In the second place, Salzman does indeed obtain by formulating a suitable Lagrangian an approximation to the behaviour of interacting masses. This Lagrangian is closely similar to one formulated by Landau and Lifshitz, which may be taken to confirm the usefulness of Salzman's metric. Incidentally, he concludes that "two-body effects can be important even in the case of a 'test' mass". Also he compares his Lagrangian with that for an analogous electromagnetic problem and pursues somewhat his analogy of gauge functions, but here the physical significance is scarcely clear. At any rate, Salzman has opened up a field in classical general relativity that will undoubtedly be further explored.

Puberty

from our *Steroid Biochemistry* Correspondent

THE mechanisms responsible for the increased secretion of androgens at the time of puberty are incompletely understood. The use of techniques for taking frequent samples of blood, the development of simple, sensitive and specific assay methods and the polygraphic recording of the stage of sleep has made possible an investigation of hormone secretion throughout a

24 h sleep-wake cycle. These techniques have shown that some hormones, for example growth hormone, luteinising hormone (LH) and follicle stimulating hormone (FSH), are secreted episodically and that their secretion may sometimes be related to the onset of a specific stage of sleep, particularly in the pubertal state. An increase of LH secretion, which may be important in initiating androgen secretion and puberty, occurring synchronously with onset of sleep was demonstrated in pubertal, and sometimes in later pre-pubertal, boys.

In a recent study (Boyar *et al.*, *J clin Invest.*, **54**, 609-618, 1974) plasma LH and testosterone concentrations were measured at 20 minute intervals throughout a 24 h period in six normal pubertal boys. In all six boys there was an increase in LH concentrations with the onset of stage 4 sleep. LH was secreted episodically and although plasma testosterone concentrations did not show such marked variations, every major secretory episode of LH was followed about 20 minutes later by an increase in the plasma testosterone concentrations. Major secretory episodes of LH could occur at times when plasma testosterone concentration was increasing and close to the maximum concentration reached during the 24 hour period, whereas during the day, although testosterone concentrations decreased, no further major episodes of LH secretions were detected. In mid-puberty similar but smaller changes were observed.

To show that the increased androgen secretion was dependent upon sleep-associated secretion of LH, subjects were studied in which sustained sleep was delayed for 3 hours. Under these conditions the first LH secretory episode again coincided with the first sustained period of stage 4 sleep and was followed by an increase in testosterone secretion. Acute sleep-wake reversal studies also confirmed this relationship, concentrations of testosterone were significantly higher during the periods asleep than during the periods awake. In contrast to these results there was no consistent increase in LH secretion with the onset of sleep in sexually mature young men and testosterone secretion occurred equally throughout the 24 hour period rather than being highest during the sleep period.

The secretion of trophic hormones such as LH from the pituitary is often regarded as being controlled by a simple negative feedback mechanism, a high secretion of trophic hormone stimulates secretion of the hormone from the target gland and this increase in turn inhibits secretion of the trophic hormone. This feedback control system seems to be operating in sexually mature young men but such a control

system does not seem to explain the changes observed during sleep at puberty when secretory episodes were often maximal at times when plasma testosterone concentrations were high. These observations suggest that at puberty the central nervous system exerts a regulatory influence which is more important than the classical feedback mechanism in controlling the secretion of LH and, indirectly androgens, at puberty. The mechanisms involved in initiating hormone secretion at this time remain to be unravelled.

Binding of streptomycin to ribosomes

from a Correspondent

STREPTOMYCIN is a well-known agent for precipitating nucleic acids. In addition to this general property, the drug is also a specific inhibitor of protein synthesis, and the inhibition is associated with the smaller (30S) ribosomal sub-particle. In *Escherichia coli*, it is known that mutations in protein S12 can confer resistance to or dependence on the drug (Ozaki, Mizushima and Nomura, *Nature*, **222**, 333-339, 1969; Birge and Kurland, *Science*, **166**, 1282-1284, 1969), and that these effects can be suppressed by mutations in proteins S4 and S5 (see for review Garrett and Wittmann, *Adv Prot Chem*, **27**, 277-347, 1973). The question therefore arises as to whether streptomycin binds to the nucleic acid or protein moiety of the 30S ribosome, and this is a problem which has given rise to some controversy.

Gorini and his co-workers believe that in the ribosome streptomycin binds specifically to the 16S RNA. In their latest experiments (Garvin, Biswas and Gorini, *Proc natn Acad Sci USA*, **71**, 3814-3818, 1974) they have compared the binding of streptomycin (SM) with that of dihydro-streptomycin (H_2SM), an analogue which can be conveniently labelled with tritium. Both drugs seem to have identical binding sites on isolated 16S RNA, as demonstrated by chasing experiments, and both induced quantitatively identical 'misreading' effects, when tested with 30S particles from various different streptomycin resistant strains of *E coli*, which bind varying low amounts of streptomycin as compared to the wild type. But the binding affinity of H_2SM is lower than that of SM, since the former but not the latter could be removed from 16S RNA or 30S sub-units by simple dialysis. This effect enabled the authors to make a very interesting experiment. 30S sub-particles from wild type or streptomycin

resistant strains were exposed to H_2SM , then the drug was removed by dialysis and the sub-particle tested in the misreading system. Surprisingly, the sub-particle showed the same extent of misreading as a control sample, which had H_2SM added back during the misreading test. Thus, streptomycin is capable of inducing a new stable conformation of the ribosome, which persists after removal of the drug.

In spite of these interesting findings, the evidence that the SM or H_2SM bind specifically to the RNA moiety of the 30S particle is still not very convincing. SM binds to 16S RNA and 30S sub-particles equally well (two moles per particle), but in an earlier publication (Biswas and Gorini, *Proc natn Acad Sci U S A*, **69**, 2141-2144, 1972) a significant binding to 50S particles and 23S RNA was also found under these conditions (0.7 and 1.3 moles respectively). Further, since the binding was measured after exhaustive dialysis rather than under saturating conditions, the number of moles bound are not necessarily saturation values. Garvin *et al* showed that SM prebound to 16S RNA could prevent the assembly of proteins under reconstitution conditions when proteins from *E. coli* B were used, whereas it had no effect when proteins from *E. coli* K were used. In the latter case, the SM remaining bound was reduced from 2 moles to 0.6 to 0.7 moles. It cannot be excluded (as the authors themselves suggest in a slightly different context) that this is due to a specific protein-mediated dislodgement of the SM from the RNA followed by rebinding to the 30S particle.

The case for binding of streptomycin to the protein moiety of the 30S particle has been put by Schreiner and Nierhaus (*J molec Biol*, **81**, 71-82, 1973). These authors distinguished two types of H_2SM binding: "Type A" (high affinity) was exhibited by 30S particles, and "Type B" (low affinity) by 50S sub-particles, and 16S or 23S RNA. Type B binding could be suppressed by high concentrations of ammonium chloride, whereas the Type A binding was unaffected, and was always considerably higher than the Type B binding. A Scatchard plot revealed that at high ammonium chloride concentration the 30S particles bound 0.8 moles of H_2SM per particle (a figure which is in close agreement with the residual binding mentioned above). Binding to 30S particles could be reduced to Type B levels by removing some of the proteins with high salt, and Type A binding could then be restored by adding back the proteins in the cold. Analysis of the individual proteins showed that S3 and S5 were the most effective in this respect. But although these experiments show a direct in-

volvement of these proteins in streptomycin binding to the ribosome, they cannot be taken as proof that the drug binds directly to the protein moiety.

So, the question of where streptomycin binds remains unresolved. At the moment the evidence seems to favour the view that the proteins are more important than the RNA, but it may well turn out that, in the complex environment of the ribosome, both nucleotide and amino acid residues are involved.

Aquatic biological pollution in Florida

from a Correspondent

OF all the ways in which man has affected the flora and fauna of the world one of the most profound has been by introducing exotic species wherever human colonies have been established. In the last century acclimatisation societies flourished with the object of introducing "beneficial" animals to various parts of the world, often with severe consequences to the native biota. Today, introductions still continue but are more often due to accidental release than deliberate introduction. A recently published study by Courtenay, Sahlman, Miley, and Herrema (*Biol Conservation*, **6**(4), 292-302, 1974) of the exotic fishes in fresh and brackish water in Florida illustrates most graphically the extent of biological pollution in this state which now contains 38 species of exotic fishes.

Thanks to its mild climate and the supply of even-temperature water from wells, Florida is the major centre in the United States for the aquarium fish industry. Some 250 fish farms exist in the state, producing nearly 80% of the pet fish for the United States. Exotic species are often unintentionally released through unprotected effluent channels, or in times of flooding. Others are dumped into open waterways when holding pools are cleared for the reception of new stock. Courtenay and his colleagues made 62 collections of fishes in central and southern Florida between July 1970 and July 1972. Thirty-eight exotic species and several hybrids between these species were found, of these 20 species and five hybrids were found to be established as breeding populations.

Not all the established exotics came directly from fish farms: some are due to release of unwanted fishes by aquarists, research workers, and to stocking by angling interests. The spread of the pike killifish (*Belonesox belizanus*) is an example. In 1957

fifty specimens were released after a medical research project was terminated, it now occurs over some 160 square miles of Dade County, and in places makes up 20% of the fish biomass, no mean feat for a slender fish of 20 cm maximum length! Others seem to be less successful—two white piranhas (*Serrasalmus rhombeus*) were caught in an (abandoned!) swimming pool in South Miami, the survivors of several after an unusually cold winter.

The walking catfish (*Clarias batrachus*) has spread rapidly and continuously since its first escape in the mid-1960s. It is an undemanding fish, capable of withstanding almost deoxygenated conditions and moderate salinity, it is also able to tolerate dessication, as well as migrating overland during rainy periods. In the dry season catfish tend to aggregate in numbers in small ponds and kill most of the animals in the pond in a few weeks.

At least eight species of cichlid fishes have become established, while others have been found. One of them, the South American black acara (*Cichlasoma bimaculatum*) is the most widely distributed exotic fish in southern Florida, and is the only exotic in the Everglades National Park. Courtenay *et al* have found that in the Fort Lauderdale area it is the dominant fish, comprising 64% of the total fish biomass. In one canal it formed 80%, but elsewhere its contribution to the fish biomass ranged from 5 to 30%. An African cichlid, the blue tilapia (*Tilapia aurea*) is now found over the greater part of northern Florida. This cichlid was claimed by the news media to be an excellent food and game fish, and was quickly spread by fishermen to other areas from its original site of introduction dating from 1961. Unfortunately it was found to be practically valueless as a game fish, and is only now being evaluated as a food fish. It has proved to be an extremely effective competitor for the native fishes, and in many eutrophic lakes now dominates the fauna.

Courtenay and his colleagues document these and the remaining exotic species in detail, but have little to say on the effects of this biological pollution on the native fauna. Undoubtedly it has been considerable, and possibly the full effects have not yet been established. They do, however, propose some remedies to stem the flood of new exotics, most particularly in drawing attention to the state statutes which already forbid the release of non-native species. Enforcement of such statutes from the outset would have prevented much of this pollution and it is greatly to be hoped that action now can contain the problem to its present, already serious limits.

Leaf protein: a beneficiary of tribulation

N. W. Pirie

Rothamsted Experimental Station, Harpenden, Hertfordshire, UK

In some cases, the protein content of the discarded haulm of crop plants may be as great as that of the harvested crop. After two false starts at the time of the Second World War, research on exploiting this and other sources of leaf protein may now be near to acceptance.

THERE are many diverse reasons for studying the composition of leaves and preparations made from them. The extent to which preparations are refined before study is equally diverse. Research on chemical taxonomy, or the processes involved in virus multiplication, calls for the isolation of leaf components in the greatest attainable state of purity; research on the nutritive value of fodders or green vegetables calls for no more fractionation than is involved in selective browsing, or trimming in the kitchen. Research on the use of bulk preparations of extracted leaf protein as a food for man and other non-ruminants is in an intermediate position. There is no need to separate innocuous components from leaf protein—there are indeed obvious advantages in retaining components such as β carotene—but the merits of leaf protein cannot be reliably deduced from analyses of the whole leaf because protein extraction is always incomplete and it must be assumed that there are differences between the group of proteins that remains unextracted and the group that is separated as leaf protein.

The history of research on leaf protein has been published elsewhere^{1,2} and will only be summarised here. Rouelle made it in 1773, Ereky suggested its use as food in 1925 and Slade repeated the suggestion in 1937. After the outbreak of war in 1939, several groups of scientists met to discuss how scientific knowledge and skill could best be used. The conclusions were communicated to those charged with care for our welfare but no attention was paid to the suggestion that leaf protein could help to alleviate protein shortage if there were a blockade. The mental climate changed after the 'fall of France' and support for the project began. In the second half of 1940, and in 1941, large-scale equipment of many types was examined to see whether any existing machinery was suitable for extracting juice from leaves.

All types had defects. Understandably, this work stopped with the arrival of 'Lend-Lease' food.

Liberating the juice

Tribulations at the end of the war, for example the ending of 'Lend-Lease' and the growing awareness that much of the world was chronically undernourished, reawakened an interest in leaf protein that persisted for 4 or 5 yr. Interest then waned and work was languishing until we received grants from the Rockefeller Foundation and later from the Wolfson Foundation. With these grants, and on the basis of the wartime studies of machinery, several extraction units were made. The design depended on the idea that liberating juice from leaf cells differs qualitatively from expressing it from leaf pulp. Separate units were therefore used for the two processes. We concluded that rubbing is more important than fine subdivision, that rubbing leaf against leaf is as effective as rubbing leaf against steel, that the layer of pulp from which juice is being pressed should be less than 1 cm thick, that pressure should be maintained for at least 7 s to allow juice to flow away from the pressed fibre, and that there is little advantage in applying a pressure greater than 4 kg cm⁻². Units conforming to these principles have been made that handle up to 5 ton of crop per hour. The pulpers run at 1,000–3,000 r.p.m. and so waste energy in creating wind, but the presses are efficient.

The advantages of liberating and expressing juice in one operation are obvious. At various times and places rollers and screw expellers have been used with partial success, as pure pressure extracts little protein from leaves. Rollers extract protein because there is some slip, which rubs leaf against leaf,

Fig. 1 Screw expeller for juice extraction

as the charge enters the 'nip', but pressure is too brief to allow juice to run away and much of it is readsorbed by the fibre. The scroll of a screw expeller rubs across the charge, this liberates juice but wastes energy in useless friction. A remodelled screw expeller in which the scroll is broken into many paddles, so that the charge is constantly rearranged and stirred as well as being pressed, should use more of the input energy to rub and tear, rather than heat, the crop. Figure 1 illustrates the principle of what is proposed. This arrangement has the additional advantage that juice is not expressed under pressure but flows by gravity through a gauze. When juice is forced through a packed mass of leaf fibre, much of the protein in organelles and their fragments is retained, and some of the finer fibre particles contaminate the juice. For quantitative agronomic studies on the yields of leaf protein attainable from different crops and systems of husbandry it will probably be better to pulp and press in separate units because it is then possible to standardise conditions more completely².

Food or fodder

Research on large-scale production of leaf protein started as a means for making human food for use in Britain and it was restarted after the war, partly for the same reason but more because it seemed likely that in the wet tropics, the yield of leaf protein would be greater than the yield of other protein concentrates. At that time the need for protein concentrates was universally agreed and the Food and Agriculture Organisation took an active interest in concentrates from such sources as oil-seeds and fish. FAO was unsympathetic towards work on leaf protein and in several publications asserted that it was unpalatable and much too expensive. Those having practical experience with properly made leaf protein knew that it was palatable—especially in countries where curry or powdered dried leaves are traditionally used as relishes. Calculations based on experience in the grass drying industry suggested that leaf protein would be as cheap as any other concentrate that was not a by-product. With FAO we were presumably up against the fundamental objections succinctly stated by Professor Mary Douglas³ "There wouldn't be time", "We couldn't afford it", "God doesn't like that sort of thing" and the ultimate "It's against Nature". The International Biological Programme was more open-minded. Research on leaf protein formed part of the national programmes of India, New Zealand, Nigeria, Sweden and the United Kingdom, and under its auspices much valuable research has been done.

Although agronomic information, and information about the effect of processing conditions on the properties of leaf protein was accumulated, there was little commercial interest. Several patents have been taken out, many of them restate facts familiar since 1773 and none cover points that are essential for commercial production. There is, or has been, commercial interest in Brazil, Eire, France, Hungary, Japan, New Zealand, Sweden, UK and USA. The actual present status of these projects is uncertain, and some of them may have failed because of the use of unsuitable equipment.

When large-scale research started it was obvious⁴ that the fibre from which juice had been expressed could be dried more economically than the forage from which it had been made. To get a ton of dry matter from a forage, 5 to 10 ton of water must be evaporated, whereas it is only necessary to evaporate 2 or 3 ton from the fibre. The product contains less nitrogen than the corresponding dried fodder but it is less lignified than a fodder with the same nitrogen content because it would have been made from a less mature crop. Furthermore, because soluble materials are largely removed from the fibre, species of leaf could be used as fodders which in the original state, are unpalatable, or even toxic to ruminants. These points were made in a note circulated by the Agricultural Research Council in 1951 and they have been stressed repeatedly (see, for example,

ref 5) since then. Even if a crop is being ensiled rather than dried extraction of juice may be prudent because it is all extracted at once, and can therefore be collected and used, instead of seeping out slowly as a polluting effluent. These advantages of fodder fractionation received little attention until the tribulations resulting from the increased price of oil focused attention on wasteful processes in general. Now, most interest is being shown in fodder fractionation as a means for conserving fodder economically, leaf protein is regarded as a by-product for feeding to pigs and poultry. There is active research at the National Institute for Research in Dairying (Shinfield), the Rowett Research Institute (Aberdeen), and the Agricultural Institute (Dublin). In some ways it is a pity that the objective has changed in this way, but the research that is being done suggests that FAO was wrong in arguing that leaf protein would be very expensive, and the experience gained will in time be used in the production of human food. Unfortunately, leaf protein will by that time have gained the stigma of being fodder and this will slightly impede acceptance by people.

Sources of leaf

Conventional crops, harvested at an immature stage, are the sources of all bulk preparations of leaf protein. At Rothamsted we prefer the cereals and clovers, while in New Zealand and USA lucerne is preferred. Batches of protein weighing a few kg have been made in Britain, India and Sweden from 20 or 30 other species—many of them normally classed as weeds. Even if species conventionally grown as sources of seed are used, it may well be that the varieties rejected by plant breeders would be better for our purpose than those that give a good yield of seed. At Rothamsted we can get 2 ton of dry extracted protein (calculated at 16% N) annually per hectare and expect to be able to get 3 ton. In India the yield is already 3 ton and it should be possible to get 5 ton. It is not certain that such large yields should be aimed at as they call for a level of fertiliser use that may not be economically sensible.

Leaves that are a by-product from a conventional crop are the ideal source of leaf protein. Potato haulm has been examined in some detail at Rothamsted, the yield of extractable protein would probably be about 600 kg ha⁻¹ at the end of July but only 100 kg ha⁻¹ in mid-September. Prudent farmers destroy the haulm at the beginning of September as a safeguard against blight, prudence would probably be more widespread if farmers realised that something valuable could be made from haulm. Bearing this in mind, and adding in the haulm from seed and early potatoes, about 60,000 ton of protein is now being wasted in Britain by destroying rather than harvesting haulm. A larger amount of protein is wasted in sugar beet tops but that source has been studied less systematically. With varieties used now, more protein can be extracted from the haulm of peas harvested for freezing and canning than is present in peas themselves. Outside leaves and other forms of waste from the vegetable industry are another large but uncertain source—uncertain because vegetables found to be surplus after reaching the shops have often deteriorated too much to be useful, and outside leaves are often damaged and would be troublesome to collect in the field. The potentialities of this source should be surveyed. One point about vegetable leaves must be stated clearly: there is no advantage in extracting protein from material that could be eaten. Few communities eat as much green-stuff as is desirable and leaf protein is more conveniently eaten in the leaf than after extraction.

Although many species now classed as weeds will be grown deliberately as sources of leaf protein, the mixed unfertilised vegetation on waste land is not a probable source. If a harvesting implement could be used on land, the land should be re-sown and properly fertilised. Water weeds are different. They are usually well fertilised and the growth in an area tends to be dominated by a single species. According to some estimates,

the annual cost of trying to control water weeds with herbicides or by mechanical destruction is £500 million hardly anything is being spent on trying to use them Enough has, however, been done to show² that leaf protein can be extracted satisfactorily from some species

Protein quality

Chloroplasts, their fragments, and other organelles begin to coagulate when leaf juice is heated to about 50° C, coagulation is complete at 70° C By separating a low-temperature coagulum, and then heating the fluid further, a green fraction containing 7–9% N and a fawn fraction containing 9–12% N can be made from most species that extract satisfactorily This may sometimes be a useful procedure, but it introduces complexities into what is otherwise an extremely simple process, the low-temperature coagulum is too soft to filter off easily When juice is heated suddenly to 70° C a dense, easily filtered curd is formed Sudden heating inactivates chlorophyllase⁶ and so prevents the formation of phaeophorbide, this was formed to a sufficient extent in slowly heated juice to photosensitise animals fed on the product⁷ The press-cake, after washing to remove soluble leaf components, should have the composition shown in Table 1 The fats are highly unsaturated This causes trouble during preservation and storage because unsaturated fat combines with

Table 1 Composition of leaf protein as usually prepared

True protein	60–70%
Lipid	20–30%
Starch	5–10%
β Carotene	1–2 mg per g
Fibre	<2%
Water soluble compounds	<1%
Ash	<3%
Acid insoluble ash	<1%

protein in a manner that makes it less digestible and keeps some of the constituent amino acids from being effectively metabolised These fats also undergo 'oxidative rancidity' This enhances the value of products such as tea and smoked fish but it is usually regarded as detrimental in other foods Dry leaf protein that has been stored in air, slowly develops a characteristic flavour As with tea and smoked fish, one learns to like it but, in the early phases of popularisation, the less flavour it has the better

Protein does not extract well from leaves rich in tannin or phenolic compounds Even small amounts of these substances, though they may not prevent extraction, combine with the protein as unsaturated fats do Differences in the extent to which these complexes were formed during extraction or storage, probably explain the differences in nutritional value that have sometimes been observed between samples of protein with similar amino acid compositions It will probably not be possible, in the course of bulk production, to prevent combination between protein and phenolic compounds That form of damage could be circumvented by selecting species and stages of growth that ensure that the leaves are relatively free from phenols

Some people dislike the green colour of leaf protein made by the simple method outlined Extracting the colour with a solvent is easy—but it adds to the cost, and the useful β carotene and unsaturated fats would then be lost Furthermore, leaf protein production has not only the merit of yielding an unprecedentedly large amount of edible protein, it is also so simple that it could be a small-scale industry in any community able to manage a tractor It will lose that merit if solvent extraction is insisted on

All leaf protein preparations for which there are reliable figures have similar amino acid compositions⁸ It is unlikely that

species differences are greater than differences between preparations made from the same species harvested at different ages or in different conditions of husbandry This uniformity is not unexpected because what is loosely called leaf protein is a mixture of many different proteins and the same amino acid deficit or excess is not likely to characterise all of them Amino acid analysis suggests that properly made leaf protein will have good nutritional value This expectation was borne out by experiments on the growth rate of chickens, pigs and rats and by brief experiments on the amount of nitrogen retained by infants fed on milk alone and on mixtures of milk and leaf protein These results have been confirmed² and extended by a six month experiment in which school children, on a diet consisting predominantly of ragi (*Eleusine coracana*), were given supplements containing 10 g of protein per day in the form of lucerne leaf protein, or sesame seed (*Sesamum indicum*) The leaf protein gave better results, assessed from height, weight and haemoglobin content, than sesame although the protein in the latter is regarded as one of the best seed proteins

Acceptability

Leaf protein should not be regarded as a medicine and eaten in the form of pills It should rather become one of the many components from which a mixed diet is made up But people do not, as a rule, think of their diets in terms of so much energy, so much protein and so on per day They eat foods with familiar appearance for traditional reasons Methods must, therefore, be found for presenting any novel foodstuff in an acceptable way Fresh leaf protein is a slightly acid cake containing 60% water and with the texture of cheese It can be pickled, salted or dried It will be most readily accepted by communities that already make regular use of green vegetables and, as already mentioned, increased use of leafy vegetables is the most sensible way of getting leaf protein eaten The next step depends on local culinary habits As a result of present-day cultural interpenetration, the food shown in advertisements in publications coming from wealthy countries are gaining prestige, while the traditional stews and gruels of much of the world, into which many novel foods, such as leaf protein, would fit easily, are losing it This is understandable but unfortunate because the foods of the wealthy are getting scarce so that expectations that are not likely to be fulfilled are being fostered It is likely therefore that novel foods, on which work was originally undertaken so that they could relieve malnutrition in developing countries, will not be acceptable there until they are manifestly used by the wealthy Acceptance will be impeded if they are first used as welfare foods or foods for the unfortunate

In some parts of the world the need for protein could be most economically satisfied by growing yeast or some other micro-organism on molasses or oil In others the best source may be a seed such as groundnut or soya But in rural tropical regions where rainfall is regular, or even excessive, leaves are the most productive source of protein these regions are at present the worst fed parts of the world Tribulation has thrice energised research on the production of leaf protein and on its use as food for people and other non-ruminants Research may now have progressed so far that the logical case for production of leaf protein is strong enough to prevail against habit and preconception It is possible, however, that a fourth jolt will be needed If economists and other prophets are to be believed, no scarcity of tribulation is imminent

Earthquake simulation by nuclear explosions

Oscar C. Kolar & Norman L. Pruvost

Lawrence Livermore Laboratory, University of California, Livermore, California 94550

A country wishing to evade a comprehensive test ban treaty could disguise a clandestine nuclear test as a natural earthquake by detonating a sequence of explosions, one of which would be caused by the device of interest

ANY discussion of a treaty prohibiting underground nuclear weapon tests (that is, a comprehensive test ban treaty, CTBT) must address the crucial issue of how to monitor whether or not the treaty is being observed. Much of the current literature ignores the possibility of schemes to conceal or disguise clandestine testing, so here we describe the reasons for believing that illicit nuclear tests, with yields up to at least 100 kilotons (kton) are feasible. Further, such tests can be carried out with little likelihood of discovery.

Seismic monitoring

The seismological literature describes numerous techniques that are directed towards identifying the source of a seismic signal as either an explosion or an earthquake. In general, they are based on features of the signals that can be explained in terms of the known gross differences in physical source mechanisms between earthquakes and single explosions. Elements of confusion enter into the use of all known discriminants, however, because the real Earth is far from an idealised, homogeneous body. Interfaces within the Earth, for instance, convert some of the compressive (P) wave energy into shear (S) waves, this tending to remove a deficiency that would otherwise be a tell-tale characteristic of explosion signals. Rayleigh and Love waves transmitted along the Earth's surface are nonetheless generally stronger in the radiation from an earthquake than in that from an explosion, but the quantitative differences are not dependable, and even though the first motion of the recorded signal from the two source types would, in principle, be distinctly different, natural background noise in general obscures it.

The salient differences between earthquake and explosion are:

- The first motion of earthquake seismic waves is rarefactional in some directions (sometimes only along rays confined to 100–200 km from the source). Seismic-wave first motions from an explosion, on the other hand, are everywhere compressional.
- P-wave trains from an earthquake are often extended in time whereas those from an explosion tend to be more compact. This results in greater P-wave 'complexity' for some earthquakes than for explosions¹.
- Seismograms from deep earthquakes frequently exhibit a phase (the pP phase) caused by reflection from the Earth's surface above the earthquake. This follows the initial downward-directed P phase by a time interval proportional to the focal depth. This interval also increases with the distance to

the detection station, an effect called 'stepout'. Explosions are seldom deep enough to exhibit a clearly separated pP phase or stepout.

- The surface waves generated by an earthquake carry relatively more energy than do those generated by an explosion of the same body-wave magnitude. Thus the surface-wave magnitude, M_s , for an earthquake is usually greater than that associated with an explosion of the same body-wave magnitude, m_b (ref 2).

Seismic evasion

We have attempted to simulate the seismic signal of an earthquake by superposing eight seismograms of a single explosion. These were identical in shape, being simply scaled versions of the explosion seismogram actually recorded at a single monitoring station. Each seismogram was delayed in time relative to the first and scaled in amplitude to correspond to that of an explosion of selected yield. This procedure was carried out for each of three different monitoring stations.

Fig 1 Geometry, firing order, yields and time delays of the eight explosions selected to simulate an earthquake

Figure 1 shows the proposed spatial and temporal separations of the shot array. In order to take travel times realistically into account we postulated a specific test site, at 37°5'N and 73°4'E in southern Tadzhik, SSR, coinciding with the epicentre of the earthquake we used for comparison. (Lack of a suitable comparison earthquake record prevented us from choosing a more realistic site, such as the area around Lake Baikal.) The azimuth, N75°E, was chosen arbitrarily and because detonation under a river would present many advantages, such as masking surface disturbances both before and after detonation, we chose a linear array of explosions.

We formed the composite, synthetic seismograms at the

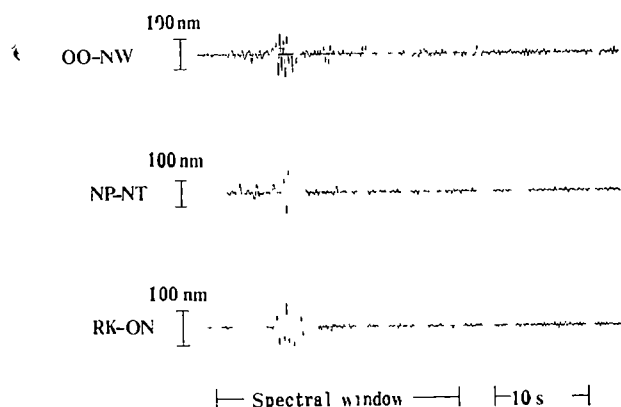

Fig 2 Composite, short-period, synthetic seismograms for the shot array of Fig 1 as they would be recorded at three seismic stations

three seismic stations Mould Bay, Northwest Territory (NP-NT), Oslo, Norway (OO-NW), and Red Lake, Ontario (RK-ON). The operations involved were

$$P(t) = \sum_{i=1}^8 p(W_i, t - t_i - T_i) + n(t)$$

$$p(W_i, t) = (W_i/100)^0 \cdot p(t)$$

where $P(t)$ is the composite, synthetic seismogram at a station and $p(t)$ is the filtered seismogram of a Semipalatinsk (Soviet nuclear test site) event as recorded at that same station. The other quantities appearing in the equations are $n(t)$, a micro-seismic noise recording, T_i , the individual travel times from explosion point to detector site, and W_i and t_i , the yields and delay times specified in Fig 1.

The United States Coast and Geodetic Survey (USCGS) reported that the explosion which generated $p(t)$ occurred on March 3, 1965 at 06 14 57 GMT. The event coordinates are 49° 8' N, 78° 1' E with depth constrained to the surface of the Earth. From the body-wave magnitude, $m_b 5.6$, we infer a yield of about 100 kton in hard rock.

The sequence in Fig 1 was not optimised for evasion. It is presented only as an example of a sequence whose seismic record would probably be identified as that of an earthquake.

Figure 2 shows the composite, short period, synthetic seismograms for the three stations and Fig 3 the seismograms of an earthquake that occurred at the postulated test site on February 2, 1965. The USCGS reported the earthquake origin time as 15 56 51.0 GMT and the magnitude as $m_b 5.8$. The two sets of seismograms are sufficiently similar that such qualitative inspection alone is unlikely to arouse an analyst's suspicions.

The following observations are based on more detailed examination of the synthetic records.

- First motions might be interpreted as refractional in two (OO-NW and NP-NT) of the three examples presented. Identification as an earthquake on this basis is unlikely, however, as the low signal-to-noise ratio makes the interpretation ambiguous.

- The three high yield explosions produce signals very suggestive of a pP phase. Again, the uncertainties are such that this could not be regarded as identifying the event positively as an earthquake. This aspect is not crucial, however, for many seismic regions that are suitable as testing sites produce earthquake signals lacking such a reflection phase.

- The body-wave magnitude would be about 5.1, equivalent to the magnitude of a 50-kton explosion in hard rock.

- The time duration of the composite P-wave signal is longer than that appropriate to a 100-kton explosion and its complexity is greater.

- We examined the Fourier spectra of the explosion on March 3, 1965 and the earthquake on February 2, 1965 at each of the three stations. The shot array spectra show no systematic pattern of peaks and nulls suggestive of source interference phenomena and overall comparison of the two sets of spectra does not reveal any other features indicative of the shot sequence.

- Rayleigh waves detected at long ranges, whether from an earthquake or an explosion, have periods chiefly in the 20-s band. Thus, the separate signals from a series of explosions occurring within a few seconds of one another will superpose constructively.

We illustrated the latter point by superposing (with itself) the Rayleigh wave signal from an earthquake which occurred in the Kermadec Islands on March 3, 1965 (The USCGS origin time and magnitude were 05 52 57.4 GMT and $m_b 4.7$, respectively). This signal was scaled, shifted and superposed in the same way as the short period signal. The amplitude of the resultant superposition is about three times larger than that of the largest individual signal. Accordingly, the surface-wave magnitude M_s of the superposition is about 0.5 units greater than that expected from a single 100-kton explosion. We used the Rayleigh waves from an earthquake because the Rayleigh waves from the explosion on March 3, 1965 were obscured by the seismic signals from the earthquake at two of the three stations and were too weak to observe at the third. This substitution does not however, affect our argument. Rayleigh waves from earthquakes have the same periods as those from explosions and we are showing only the effects of superposition.

The net effects of modifications to body and surface-wave magnitude are shown in the M_s , m_b plot, characteristic of the postulated shot array region (Fig 4, adapted from Fig 7 of ref 3). The signal from a single 100-kton explosion would be expected to lie within box 1 (the width of which is intended to be representative of the spread in M_s values associated with a given m_b). The body-wave magnitude of the superposition is reduced to 5.1 which would result in an M_s , m_b value lying within box 2 provided the surface wave magnitude were that corresponding to a single 100-kton explosion. Enhancing M_s by 0.5 units (the effect of constructive interference of the surface waves) moves the point into box 3. This falls comfortably within the earthquake population.

Thus the signal, when subjected to typical discrimination analysis, appears more earthquake-like than explosion-like.

Practical considerations

We have studied the engineering, logistic, camouflage and diagnostic considerations that would be crucial to the actual conduct of such a clandestine test. Although a detailed discussion

Fig 3 Seismograms showing P waves of an earthquake near the Russia-Afghanistan-China border intersection as recorded at three seismic stations

Fig 4 Surface-wave magnitude (M_s) against body-wave magnitude (m_b) for a population of earthquakes and explosions and for the eight-shot array discussed here. All events are from a region around the assumed test site. Adapted from ref 3. ●, Explosions, ○, earthquakes

lies outside the scope of this article, we conclude that none of these matters would present serious problems.

Briefly summarising, camouflage might well be accomplished by detonating the explosives under a river bed. We have carried out a complete feasibility study of this unconventional operation. Including the conceptual design of a suitable drill barge and its associated drilling equipment, the development of complete pre-shot and post-shot operational plans, the development of a drilling plan, including operation of a drill-barge, design and emplacement of a canister containing both device and diagnostics and device detonation. The important result was that the whole operation could be accomplished with current technology, albeit assuming the high level of technical competence in the domain of nuclear testing to be expected of mature nuclear powers.

The operational concept was shown to evade all possible detection threats, for example

- Increased river activity is accounted for to the local populace by initiation of a suitable construction project
- Overhead surveillance is thwarted by carrying out drilling or other identifiable operations only at night
- Drilling chips are discharged downstream, in deep water
- Surface expressions are averted by detonating the explosions underwater

We acknowledge that such an operation would call for special care and effort and would entail greater expense than non-prohibited tests. In the feasibility study alluded to we also considered these matters. We are confident that the additional difficulties resulting from the clandestine nature of the test can be overcome at acceptable levels of expense and effort. With dedication and suitable inducement a test crew of reasonable size (~100) could carry out the entire operation in about four months. This conclusion is again based on US test experience and short extrapolations from that. We estimated that costs would not exceed those of a single conventional test by more than a factor of 30. Thus, although such a test would be expensive, its cost need not deter a determined evader.

If, on the other hand, the drilling were done on land, avoidance of the visible or other detectable effects of a clandestine explosion would become a prime requirement. Potential effects include, primarily, various alterations of ground surface contours over the explosion and the release of radioactive effluents. A careful evader with test experience could predict such effects with confidence.

Surface collapse craters are common and very visible phenomena at underground nuclear explosion sites⁴. Their probability of occurrence depends on the local rock type as well as the yield and depth of the explosion. Experience in the United States shows that a burial depth (in metres) of at least 300 times the cube root of the yield (W), expressed in kton, will prevent surface cratering regardless of the rock type.

Other visible effects can include minor surface cracking related to ground disturbances and settlement, and surface expression of fault motion stimulated by the explosion. These are observed within a few kilometres of US tests, where the typical burial depth is in the range of $120W^{1/3}$ (ref 5). Offsets of a few centimetres are common and cases of dislocations measuring a metre or more have occurred. Burial at greater than normal depth would probably, though not certainly, eliminate these effects. Gasbuggy, Rulison, and Rio Blanco, the three deep US nuclear explosions fired to test stimulation of natural gas production, produced no observed fault motion or surface cracking. Their depths of burial were all at least $400W^{1/3}$ m.

Venting of radioactive material would in all likelihood be completely absent and at most would be limited to trace seepage of gases, detectable only by sensitive survey instruments at the explosion site. Present containment techniques in use by the United States are highly successful at normal burial depths and would unquestionably assure containment at the greater depths appropriate to a clandestine explosion.

Finally, and very briefly, precautions of a practical nature which an evader would likely take are

- Carry out the test in an area of low population density with at least moderate seismicity
- Use the smallest possible test crew
- Devise a cover operation to deceive the local populace and provide an excuse for whatever relocations might be necessary
- Detonate before dawn to catch most of the local population asleep. Avoid detonation on an even hour, half hour or minute, as has been common practice in previous non-prohibited tests
- Issue a routine earthquake announcement. The details would be misleading (but not so misleading as to arouse suspicion)
- Select highly reliable explosives to be included with the test device in the explosion sequence (We did, however, study the effect of failure of any one of the eight shots, but it is small and does not change the conclusions presented here.)

We believe that these precautions, and others, can be followed by a determined, resourceful evader with previous field test experience and a stockpile of proven, reliable weapons.

Reassessment

We have outlined in this article a possible way of carrying out clandestine nuclear tests. The arrangement produces a seismic signal that would be identified by seismic analysts as that of an earthquake on the basis of the M_s , m_b criterion. All other criteria considered are at least consistent with, or suggestive of, identification of the event as an earthquake.

We made no attempt to optimise yield, number of explosions or any other parameter, or to identify the maximum yield that could be tested. Even so, we demonstrate a substantial enhancement of yield capability over the detection threshold for an undisguised test.

Further, the maximum yield permitted by this evasion scheme would still not tell the whole story. Weapons of still higher operational yield could be developed and stockpiled if an evader were willing to risk extrapolating their expected performance from partial-yield experiments.

We are aware of intensive current work on new discriminants, for example, Love-to-Rayleigh spectra ratios, radiation patterns and newer techniques for depth determination. These newer discriminants are generally incompletely developed, but even if they were applied the superposition presented here would be classified as an earthquake according to present standards. It met the M_s , m_b criterion and, as discriminants are used at present, satisfaction of just one discriminant results in identification (This is because any requirement that more than one criterion be satisfied would preclude identification of most events).

We believe that recent statements concerning identification of nuclear tests in the 10-kton range must be understood to

apply only to the current open mode of underground testing. If a CTBT were to emerge, the relevant seismic monitoring capability should take into account competent efforts at evasion. We suggest that such a reassessment must be factored into the proposed safeguards for a CTBT.

We thank K. Bandtel for suggesting this article. C. Boardman, J. Duncan, D. Nielsen, and D. Springer made essential contributions. C. Archambeau, E. Herrin, D. Davies and the Lincoln group at MIT, H. Rodean and J. Savino provided valuable data and ideas. C. Romney and F. Pillotte have been especially helpful. The seismic calculations presented here were

carried out by Theodore Cohen and other workers at the Seismic Data Analysis Center, Teledyne, Geotech. The work was done under the auspices of the US Atomic Energy Commission and supported by the Nuclear Monitoring Research Office of the Defense Advanced Research Projects Agency.

Institut Max Von Laue-Paul Langevin, BP 156 Centre de tri, Grenoble, Cedex 38042, France

New structural data have been obtained from neutron scattering studies of chromatin. The concentration-dependent meridional peak at 10–11 nm comes from the interparticle spacing of a subunit structure. Peaks at 5.5 and 3.7 nm have a different contrast behaviour to those at 11.0 and 3.7 nm showing that histones and DNA have a different spatial arrangement in the subunit. A globular model in which apolar segments of histones form the core surrounded by DNA complexed with the basic segments of histones agrees with the data.

STRONG evidence for a basic structural repeat in eukaryotic chromosomes comes from the observation of a series of rings at about 11.0, 5.5, 3.7, 2.7 and 2.2 nm in the X-ray patterns of native and reconstituted chromatin^{1–8}, they do not seem to have been observed in the X-ray pattern of DNA nor in the X-ray pattern of total histone. In 1964, Wilkins proposed a model of a uniform supercoil with a pitch of 12.0 nm and an outer diameter of 13.0 nm to explain this characteristic X-ray pattern, and in the model calculations it should be noted that only the X-ray scatter of the DNA component was considered⁸. Another, more irregular supercoil model (pitch 4.5–7.0 nm, outer diameter 8.0–12.0 nm) has been proposed⁹. An extension of the idea of the supercoil is a polyhelical model¹⁰. Several authors have proposed a globular subunit structure for chromatin^{11–15}. 'Linear arrays of spherical chromatin particles have been observed'^{11–13}, of about 7.0 nm diameter joined by threads 1.5 nm diameter. This 'particles-on-a-string' model is supported by further observations: endonuclease digestion of chromatin gives DNA pieces in integral units of about 200 base pairs^{16–18}, and nuclease digestion a basic subunit of 205 base pairs and a second degradation subunit of 170 base pairs¹⁹. It has also been postulated¹⁸ that tetramers of histones (H3 and H4), observed in histone gently dissociated from chromatin^{20–21}, associate with 200 base pairs to give a subunit of chromatin.

Clearly, additional data are required and for this reason we have used neutron techniques. Small angle neutron scatter

techniques have particular application to studies of structures of complex biological systems at low resolution^{22–25}. The very large difference between the average neutron atomic scattering factors per atom for H₂O (-0.06×10^{-12} cm) and D₂O ($+0.63 \times 10^{-12}$ cm) allows the scattering from all biological molecules to be contrast-matched. Figure 1 shows that neutron scatter from DNA is expected to be matched at about 63% D₂O and that of

Fig 1 Computed neutron scatter from the components of chromatin. Mean neutron atomic scattering amplitude (b) against percentage D₂O in the D₂O + H₂O mixture for H2B, H2A, H4 and H3 histones together, and for DNA. The plots for histone and DNA are sloping because of the exchange of labile protons with deuterium and thus is proportional to the amount of D₂O in the aqueous mixture.

histones at about 37.5% D₂O. In practice, however, using hydrated H1-depleted histone films, the matching occurs at 44% D₂O. The large difference in the proportions of D₂O required to match histones and DNA provides an opportunity to study the relative disposition of histones and DNA in chromatin.

Fig. 2 Contrast variation of the radial distribution (averaged over 360°) of neutron scattered intensity for total chromatin films at 50% w/w concentration, $1/d$ is the reciprocal of the equivalent Bragg spacing (given below). The chromatin was isolated from fresh calf thymus by the method of Panyim *et al.*³⁶ Chromatin and H1-depleted chromatin³⁷ were treated with 0.5 M HCl for 2 h at 4°C , precipitated with six volumes of acetone and washed three times with acetone. After vacuum drying the histones were analysed by polyacrylamide gel electrophoresis³⁸. The protein/DNA ratios were measured by infrared spectroscopy, with suitable corrections as reported previously³⁹, which also shows any sample impurities. Experiments were carried out at 6 \AA with the small angle scattering equipment (NLS)²⁴ at the ILL, Grenoble. The graphs have been redrawn on different scales, the factors by which the originals were changed being indicated on the appropriate curve. The percentage D_2O is given in each case.

Contrast variation studies in chromatin

Contrast variation experiments, using H1-depleted and total chromatin gel equilibrated with vapour from mixtures of H_2O and D_2O , provided results over a range of relative humidities (r.h.). Those for 50% w/w concentration of chromatin at 98% r.h. are shown in Fig. 2. Although the resolution is lower than for X-rays, the curve which approximates to the X-ray patterns is that at 10% D_2O , which is also approximately the composition at which the solvent neutron scatter is almost zero. The effect of changing the $\text{H}_2\text{O}/\text{D}_2\text{O}$ ratio is striking. At 100% D_2O the 10.0 nm (approximate) ring is dominant and there is a clear ring at 3.7 nm. As the D_2O content is reduced the intensity of this 10.0 nm ring weakens to become zero at 30% D_2O , after which it increases again. A plot of the square root of the intensity is linear and goes through zero at 30% D_2O . The background scatter underlying the diffraction rings also levels at the same $\text{D}_2\text{O}/\text{H}_2\text{O}$ ratio. The 3.7 nm ring behaves similarly but retains a low intensity at 30% D_2O (Fig. 2). The 5.5 and 2.7 nm rings, however, are strongest at 0% D_2O and weaken in intensity with increasing D_2O content, until the 5.5 nm ring is no longer observable and the 2.7 nm ring is very weak. Similar results were observed with H1-depleted chromatin at about 9% w/w, except that the intensity of the lowest angle ring is reduced to zero at about 44% D_2O . At 77% w/w, the lowest angle ring is found at 9.0 nm, reaching zero intensity at 0% D_2O . The 10.0 nm ring seems to be a Bragg peak in a

region where scattering comes mainly from the protein component of the chromatin subunit. The other peaks may be part of the Fourier transform of the individual subunits, the 5.5 and 2.7 nm peaks arising from the transform of the DNA component and the 3.7 nm peak from the arrangement of proteins in the subunit. The background scatter also seems to come from the protein component.

One of the chromatin films used was stretched and the neutron scatter pattern recorded after equilibration in 98% r.h., 100% D_2O . Figure 3 shows that the 10.5 nm ring has a meridional orientation and the background scatter a strong equatorial orientation. With other camera settings, this equatorial scatter extended to about 4.0 nm equivalent spacing.

Concentration dependence in H_2O and D_2O

There is a marked concentration dependence of the intensities of the low angle X-ray rings of chromatin^{1,2,6}. With increasing concentration the ring at about 11.0 nm weakens and disappears, whereas the higher angle rings in sequence initially increase in intensity then weaken and disappear. Finally, in the dry state two rings are found at about 8.0 and 4.0 nm. Attempts have been made to explain this behaviour by changes in the packing of regular supercoils⁵. With neutrons a similar behaviour is observed for chromatin in H_2O (Fig. 4). The neutron ring at about 10.5 nm weakens with increasing concentration reaching zero intensity at 77% w/w and re-appearing at 8.0 nm at the highest concentrations. At 77% w/w, the background scatter underlying the diffraction rings also levels in a manner similar to the contrast matching against $\text{D}_2\text{O}/\text{H}_2\text{O}$ ratios described above. Again, the resolution is lower than for X-rays, the intensities in the other rings seem to move to higher angles with increasing concentration. In D_2O , there is a markedly different concentration dependence of the intensities of the diffraction rings (Fig. 5), crucial to our understanding of the chromatin diffraction patterns. In contrast to the behaviour in H_2O the lowest angle ring does not go through zero intensity with increasing concentration. Because of the similarity of H_2O and D_2O this difference, and therefore the concentration dependence of the intensities of both X-ray and neutron rings in H_2O , cannot be ascribed to structural changes. With increasing concentration, however, the peak moves from about 10.5 nm to 8.4 nm, consistent with closer packing of the chromatin subunits. Throughout the changes in D_2O , the 3.7 nm peak is constant, indicating a different origin to the variable 11.0 nm ring.

Neutron scatter from histone and DNA

We were particularly interested in the contrast variation of the low angle scattering from histone. Neutron scatter curves from films of total histone and H1-depleted histone show a clear

Fig. 3 Neutron scatter pattern (at 98% r.h. D_2O vapour) from an H1-depleted chromatin film which was stretched to produce orientation in the vertical direction. The pattern was reproduced on a display screen representing about 4,000 detectors of equal sensitivity over the area of the picture. The screen is 'brightened up' over a restricted range of detector counts. Wavelength, 12 \AA .

Fig. 4 Concentration dependence of the radial distribution (averaged over 360°) of neutron scattered intensity in H_2O for total chromatin. The distribution is superimposed on a background of incoherent scattering (not shown). The results for H1-depleted chromatin were very similar. The chromatin was depleted in histone H1 using an ion exchange resin⁸⁷ (Bio-Rad AG50W-X2) with a final buffer concentration of 0.65 M NaCl, 10 mM Tris-HCl, pH 7.

diffraction peak at 13.0 nm (equivalent Bragg spacing) in hydrated histone films. This ring is probably related to the scatter at 11.0 nm in native chromatin and reached zero intensity at about 44% D_2O content, a similar result to that obtained for the low angle scatter peak from H1-depleted chromatin mentioned above. We have also studied the contrast behaviour of films of DNA hydrated at 100% r.h. A strong neutron scatter peak corresponding to the packing of DNA behaved in a manner similar to that exhibited by the 2.7 nm peak, with change of D_2O content, shown in Fig. 2.

Discussion

The use of 'contrast matching' in low angle neutron scatter studies of chromatin shows that the low angle rings at about 11.0, 5.5, 3.7 and 2.7 nm originate not from the spacing of a single structural repeat and its higher orders (regular supercoil

model) but from different spatial arrangements of the histones and the DNA. The arrangement of histones, H2A, H2B, H3 and H4, provides a broad distribution of neutron scatter which is strong in the region of the concentration-dependent 10–11 nm peak and also has a strong component at 3.7 nm, whereas the DNA component contributes to the rings at 5.5 and 2.7 nm. Thus the region of neutron scatter to which the two main

Fig. 5 Concentration dependence of the radial distribution (averaged over 360°) of neutron scattered intensity in D_2O for total chromatin. $X\%$ is the percentage concentration of dry chromatin in the films, obtained by bringing the films to a constant weight in a vacuum after the experiment. The dotted curves represent vertical magnification by a factor of 6.

Fig 6 Schematic representation of a possible model for the chromatin subunit structure. The protein core is a complex of the apolar segment of the four histones indicated, the basic segments of the histones being complexed with DNA on the outside of the unit. Histone H1, possibly on the outside of the chain of globular subunits, may have a cross-linking role, either between subunits in the same chain or between subunits in different chains. The pitch of the DNA, which need not be uniformly coiled, is 5.5 nm with a mean diameter of about 10 nm.

components of chromatin contribute can be largely separated even though it is strictly a case of adding together all the scattering vectors of the whole structural unit to obtain intensities.

Clearly the concentration-dependent ring at about 10.5 nm arising from protein scatter can be attributed to the interparticle spacing of the proposed subunit structure for chromatin. Together with the low angle ring obtained from the neutron scatter of total and H1-depleted histone, this suggests that histones H2A, H2B, H3 and H4 comprise a multimeric protein unit, occupying a separate region of space to the DNA component. Neutron scatter data suggest that DNA is external to the histone. The equatorially oriented low angle scatter distribution (Fig 3) extends out to equivalent spacings as high as about 4.0 nm, using an analysis analogous to Clark-Jones²⁶ this may be interpreted in terms of the equatorial transform of the individual subunits in the string. The contrast matching experiments show that this scatter and the background scatter in more dilute solution comes from the low angle component of the protein transform, which is presumably at a higher angle than the low angle component of the DNA transform. This would be expected from a globular unit containing a core of histone surrounded by DNA. It is not clear whether this protein core is spherical or extended along the fibre direction, the directional properties of this structure will involve contrast and concentration studies on oriented chromatin films to seek out zeroes in the subunit Fourier transform (*c f* 40).

The difference in concentration dependence of the intensities of the low angle rings in H₂O (Fig 4) compared to D₂O (Fig 5) could be explained by the contrast matching of the protein unit against a matrix of hydrated DNA. Histones contain highly basic segments and NMR studies show that these segments (for example, 1-31 of histone H4, 1-31 of histone H2B, 1-25 of histone H2A) are the primary sites of interaction with DNA, whereas the complementary apolar segments (in which the secondary structure can be induced by salt) are the sites of histone-histone interaction^{27,28}. Similar interaction of the apolar segments would be expected in the observed interaction between different histones²⁹. The neutron data clearly show regions of protein separate from DNA, we propose

that these regions are complexes of the apolar segments of the histones H2A, H2B, H3 and H4. When the chromatin is diluted water will preferentially hydrate the DNA, in the neutron scatter, therefore, the apolar protein cores will be contrasted against a matrix of hydrated DNA. Figure 1 shows that the protein neutron scatter density lies between that for DNA and water, only in H₂O and at low D₂O contents. As the H₂O hydration of DNA changes with concentration the scatter of the hydrated DNA, at a particular state of hydration, can therefore match that of the protein. With D₂O no such concentration-dependent contrast matching would occur because the neutron scatter densities of both DNA and D₂O are greater than that of the protein. The 3.7 nm ring, attributable largely to protein scatter, does not move during hydration. This possibly arises from the arrangement of proteins in the core of the subunit, which is unaffected by hydration. A core type subunit model has already been suggested^{18,30}.

The DNA component of chromatin at the lower concentrations contributes scatter to the rings at 5.5 and 2.7 nm, each chromatin subunit possibly contains 1.5-2 turns of a coil of DNA (pitch 5.5 nm) wound on the outside of the histone core. Other DNA folds are however possible.

A schematic representation of our model is shown in Fig 6. A DNA subunit length of 205 base pairs could be accommodated in the model if the mean diameter of the DNA coil is about 10.6 nm. Since part of this DNA forms links between the subunit, the diameter of the DNA coil would be correspondingly reduced, depending on the length of these links. It is possible that the 170 base pair DNA unit observed¹⁸ forms part of the subunit, the additional 35 base pairs forming the link.

Very lysine rich histone H1, is not involved in the subunit structure giving the low angle rings⁷ and many studies have implicated H1 in a cross-linking role in chromatin. Further, the radius of gyration of chromatin is reduced after specific removal of H1 (ref 32), suggesting that this histone is on the outside of the chain of globular units. The constant value for the radius of gyration of chromatin in H₂O and D₂O proposed³², is not inconsistent with this model if both H1 and non-histone proteins were located on the outside of the DNA coil. It is now clear, however, that detailed neutron scatter studies are required at about 44% D₂O.

Chromatin is thought to consist of a string of such globular units with unknown orientations. The packing of such units in the chromosome is mediated through protein (probably H1) interaction, similar interactions probably take place between isolated chromatin subunits. In this case, therefore, the diffraction pattern of the isolated units would be similar to those of native chromatin since a diffraction peak corresponding to the lowest angle ring would arise from simple aggregation of the subunits³³.

An attractive general hypothesis concerning the control of chromosome structure through the cell cycle is that chemical modification of histones are involved. With only five major histones a chemical modification of any histone will modify the interaction of that histone with DNA throughout the genome. Further, these chemical modifications affect the state of charge of basic residues, or of serines and threonines, which are located in or close to the basic segments of the histone molecules. It may be significant that in the model proposed above the basic segments of the histones are complexed with DNA on the outside of the globular unit and are thus accessible to enzyme modification or enzyme attack. Phosphorylation of histone H1 has been implicated in the initial stages of the process of chromosome condensation and control of cell division^{31,34,35}.

We thank Drs S. Bram, B. G. Carpenter, H. Matthews, H. Molgaard, R. M. Stephens, D. Worcester (Harwell) and Mrs S. Danby for their assistance and many helpful discussions, and Mr J. Haas and Mr U. Hrabak for solving our computer problems. The British Science Research Council and the Institut Max Von Laue-Paul Langevin, Grenoble, France, have supported this work.

letters to nature

Nature of Her X-1

IYENGAR *et al*¹ have reported observations of hard X rays from Her X-1, which seem to set an upper limit of 10% on the pulsating component in the energy range 20 to 45 keV. I offer a simple explanation that does not require the additional source of X rays postulated by Iyengar *et al*.

In a strong magnetic field with $\omega \ll \omega_B$ (where ω is the photon frequency and $\omega_B (= eB/m_e c)$ is the electron gyro-frequency) the Thomson scattering cross section is reduced by $\sim (\omega/\omega_B)^2$ from its zero-field value for electromagnetic waves with E-vector pointing perpendicular to the field lines (because the electrons are constrained to oscillate along the field lines). In a magnetised plasma with $\omega \ll \omega_B$, the E-vector of the 'extraordinary' mode will essentially always be perpendicular to the magnetic field, whereas for the 'ordinary' mode this will be the case only for propagation along the field lines² thus the reduction in the Thomson scattering cross section occurs in general only for the extraordinary mode. I now refer to the model widely used to explain the X-ray pulsing from members of binary systems (specifically Her X-1 and Cen X-3), in which a rotating neutron star with a non-aligned magnetic field accretes material from its companion, the magnetic field channelling the infalling matter toward a 'hot spot' near the surface of the neutron star³⁻⁶. As I show elsewhere⁷, the gravitational energy carried by the infalling ions is transferred to the electrons in a stationary background plasma through Coulomb collisions, these electrons then produce the bulk of the observed X-ray emission, the mechanism depending on the strength of the magnetic field at the neutron star surface, B_0 . Should this field be so strong that $\hbar\omega_{B_0} \sim kT_e$, then the quantisation of the electron orbital energy must be taken into account. In particular, if $kT_e < \hbar\omega_{B_0}$ the only state energetically allowed to most electrons is the ground state, so that these electrons are constrained to move parallel or antiparallel to the field lines, and cannot emit cyclotron radiation.

It may now be argued that photons with frequencies $\omega \ll \omega_{B_0}$, produced at the base of the accretion funnel, will be markedly beamed in a direction perpendicular to the field lines. They are emitted by nonrelativistic electrons undergoing one-dimensional bremsstrahlung, so that the original radiation pattern is dipolar with maximum intensity perpendicular to the field lines (note that the photon frequencies far exceed the plasma frequency, and that the emitted photons are predominantly linearly polarised and in the ordinary mode), and the scattered radiation

pattern will be similar. Furthermore, even though the Thomson scattering cross section is reduced for both modes propagating along the field lines, a photon is not likely to escape upward through the accretion funnel, not only because it encounters far more material in that direction, but also the mean free path against Thomson scattering rapidly decreases in that direction because of the fall-off of the magnetic field, so that the photon tends to random walk downwards. Indeed, if one assumes that within the accretion funnel the plasma flows along the field lines at the free-fall velocity, then the steady state continuity equation yields

$$n(r) \sim n(R)(r/R)^{1/2} [B(r)/B_0] \quad (1)$$

where r denotes radial distance from the centre of the star and R the radius of the star, so that for reasonable magnetic fields $B(r)$ the fall-off of density in the accretion funnel, $n(r)$, is sluggish compared to that in, for example, the emitting region itself⁷. On the other hand, above the emitting region, the scattering cross section increases as $\sim (\omega/\omega_B)^2$, so that the photon mean free path decreases as

$$l_{\parallel}(r) \sim l_{\parallel}(R)(R/r)^{1/2} [B(r)/B_0] \quad (2)$$

until $B(r) \rightarrow \omega m_e c/e$ and the Thomson scattering cross section relaxes to its zero-field value, at which point the photon mean free path begins to increase inversely as $n(r)$. As an example, for a dipole field $B(r) \propto r^{-3}$, one has $n(r) \propto r^{-5/2}$ and $l_{\parallel}(r) \propto r^{-7/2}$. The beaming will be further enhanced through the conversion of ordinary into extraordinary mode photons in some scatterings, the latter then escaping easily if they are directed approximately perpendicular to the axis of the accretion funnel (A more detailed investigation of photon diffusion through plasma in a superstrong magnetic field is being carried out by M. Rosenberg and Y.-M. W.) It is then clear that the radiation must emerge near the base of the accretion funnel in a markedly fan-shaped beam (exhibiting, incidentally, substantial linear polarisation).

On the other hand, at higher frequencies, that is for $\omega \rightarrow \omega_{B_0}$, the electrons are no longer constrained to move one-dimensionally while the Thomson scattering cross section rises to its zero-field value for both modes of propagation, and the beaming should be at least partially smeared out (The magnitude of this effect will depend on, for example, the density gradient transverse as compared to that parallel to the axis of the accretion funnel). I assume that the pulsating component of the Her X-1 emission vanishes between 20

and 45 keV, and obtain a rough estimate of the magnetic field at the star surface by setting $20 \text{ keV} \lesssim \hbar\omega_{B_0} \lesssim 45 \text{ keV}$, from which $2 \times 10^{13} \text{ gauss} \lesssim B_0 \lesssim 4 \times 10^{13} \text{ gauss}$. Interestingly, Iyengar *et al* claim that the data for the entire energy range 2–80 keV can be fitted by a bremsstrahlung spectrum with a temperature of about 23 keV. On the basis of the above considerations, one would expect a bremsstrahlung spectrum below $\sim \hbar\omega_{B_0}$, although the shape of the spectrum above $\sim \hbar\omega_{B_0}$ is difficult to determine, one might expect a steep fall-off because of cyclotron emission.

I emphasise that the absence or near absence of hard X-ray pulses from Her X-1 claimed by Iyengar *et al* is as yet unconfirmed by any other group. Indeed, Holt *et al*⁸ find that the Her X-1 pulsed emission above $\sim 12 \text{ keV}$ is characterised by narrower peaks than that at lower energies (with no apparent difference in the ratio of pulsed to non-pulsed emission), in addition, they find a sharp cutoff in the (total) spectrum at $\sim 24 \text{ keV}$ which seems irreconcilable with the high energy data of Iyengar *et al*. If the surface field on Her X-1 is relatively weak, so that $\omega > \omega_{B_0}$ over the observed range of energies, then the dominant emission mechanism would be magneto-bremsstrahlung at a rate determined by the collision frequency (since the cyclotron decay time is far shorter than the Coulomb deflection time for an electron) giving rise to a soft energy spectrum⁷, and in this case the pulses at low energy might well be somewhat broader than those at higher energy because of the emission of soft X-rays above the star surface (for example, cyclotron emission by electrons spiralling down the accretion funnel).

I thank K. M. Rosenberg, P. C. Joss and J. E. McClintock for comments.

Model for 1.24 s X-ray pulses in Her X-1

THE 1.24 s X-ray pulses observed in the 2–20 keV region from Her X-1 are thought to arise from matter being accreted on to a rotating, magnetic neutron star. The pulse shape has been studied by several groups^{1–3}. More than 65% of the emission is concentrated in 0.4 of the duty cycle. The emission in this interval is usually double peaked, though it is sometimes single peaked¹ or asymmetrical^{2,3}. The pulse profile varies on time-scales of hours to days¹, and from pulse to pulse (my unpublished work with T. Chetani and R. Giacconi).

The pulsed emission is usually thought to be produced by a process analogous to that of radio pulsars. X-rays are emitted in a directed fan beam from the magnetic poles of the neutron star, which scans a circle in the sky as the star rotates. The Earth is in the line-of-sight of the beam only during a portion of each 1.24 s period. The double-peaked feature can be accounted for qualitatively by assigning particular values to the angle between the rotation axis and the magnetic axis (angle α), the angle between the rotation axis and the line-of-sight (β), and the width of the emitted fan beam². This model relies on two important assumptions: highly anisotropic X-ray emission from the base of the accretion column (beam width $\approx 25^\circ$), and constant luminosity at the source. A theory of highly beamed emission caused by synchrotron processes

Fig 1 Diagram of Her X-1 with accretion disk. Magnetic funnel is shown here out of accretion plane. Neutron star is not to scale.

has been developed in support of this model⁴. But it is not clear that some proposed alternative models^{5–7} can account for the requisite narrow beam width. Beaming in these models is difficult if the magnetic moment of the neutron star is greater than $2 \times 10^{29} \text{ gauss cm}^3$ (ref. 8). The first assumption is thus open to question.

The second assumption is called into question by the possibility that the amount of matter falling into the accretion column will vary within each period. The accreting matter spirals into the neutron star in a thin plane until it is caught by the magnetic 'funnel' at the Alfvén radius⁸ ($R_{\text{Alf}} \approx 10^8 \text{ cm}$), from which it is accelerated directly on to the surface. For most choices of α and the angle between the rotation axis and the accretion plane (γ) the magnetic funnel will not lie continuously in the accretion plane but will sweep in and out of it during each rotation (Figs 1 and 2). Since the plasma density in the accretion plane is much greater than the density of matter distributed generally around the magnetosphere, one would expect well defined spurts of dense plasma to fall down the accretion column as the funnel passes through the plane. If these density variations arrive at the base of the accretion column intact, the X-ray emission will be pulsed. For many values of α and γ the funnel will pass through the accretion plane twice in each period, thereby providing for the double-peaked pulse structure (Fig. 2a).

So I propose that the 1.24 s pulses originate from luminosity variations at the source arising from time-varying accretion rather than from the passage of a beam of constant intensity past the Earth.

Unlike the conventional model, my model does not depend on any particular emission mechanism or beam width, puts no restriction on β , and takes cognisance of the anisotropic distribution of accreting matter around the magnetosphere.

This model is only feasible in certain conditions. First, as with the standard model, α cannot be 0° . This condition is met by most known neutron stars. Second, in order for the magnetic funnel to move in and out of the accretion plane, γ must not be 90° . Though it is frequently claimed that $\gamma = 90^\circ$, my condition will hold if the rotation axes of Her X-1 and HZ Herculis, the companion star, are not aligned. They might have been misaligned before the collapse of Her X-1 or γ might have been changed during the collapse. It has further been suggested that if HZ Her were once illuminated unevenly by X-rays from Her X-1, the accretion disk would permanently lie out of the orbital plane, resulting in $\gamma \neq 90^\circ$. Two forces might be thought to force the rotation axis perpendicular to the accretion disk: relativistic frame dragging and torque exerted by the accreting matter. The frame-dragging effect will significantly alter the orientation of the disk only if $R_{\text{Alf}} \lesssim 2 \times 10^7 \text{ cm}$ (ref. 10). The torque will be directed against the magnetic axis rather than the rotation axis. Thus, unless the magnetic and rotation axes align themselves or the neutron star wobbles, the magnetic funnel will still sweep in and out of the accretion plane during each rotation.

Next, it is assumed that the movement of the magnetic funnel through the accretion plane does not seriously distort

the structure of the accretion disk. This requirement can be verified only when more is known about the interactions at the Alfvén radius.

Finally, this model imposes some conditions on the properties of the plasma in the accretion column. Limits on turbulence and convection during the descent are required so that variations in the density of the infalling plasma are not smoothed out beyond the timescale of features observed in the Her X-1 pulse profile (rise time ≈ 50 ms). Since the total free-fall time from R_{Alf} to the surface of the neutron star is ≈ 100 ms, this condition would be violated only by very largescale effects in the column or by significant delays at shock fronts or deceleration zones. The model further demands that each spurt of plasma cool within ≈ 50 ms. This has been substantiated by preliminary calculations⁸.

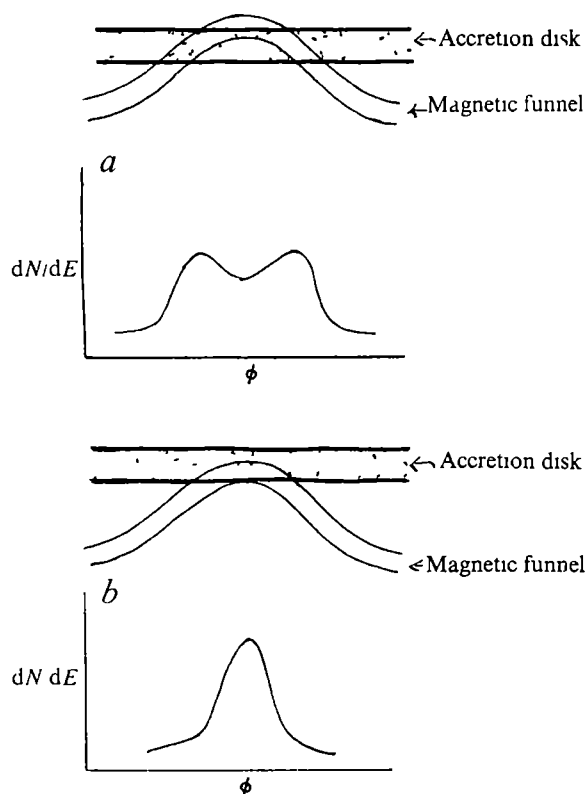

Fig. 2 Relative position of magnetic funnel and accretion disk as a function of phase, and the resulting pulse shape *a*, double-peaked pulse, *b*, single-peaked pulse after precession of the neutron star or accretion disk

None of the conditions listed here seem insurmountable, though several may warrant further investigation.

Since the rotation axis and the accretion plane are not perpendicular in this model, either the neutron star or the accretion disk will be precessing. Precession has been proposed by several authors as the source of the 35-d periodicity of Her X-1^{9,11}. Evidence for variation in the shape of the 1.24 s pulse across the 35-d cycle would provide strong evidence for the present model. Qualitatively, it predicts the secondary minimum to be more pronounced in the middle of the 9-d 'on' state, and more single-peaked pulses to be observed at the beginning and end of each 'on' state (Fig. 2*a* and *b*).

Short term variations in pulse shape and intensity ($\approx 1-10$ s) observed in Uhuru sightings (unpublished) of Her X-1 may be explained in this model in terms of fluctuations in accretion disk density. The fluctuation frequency is expected to be roughly equal to the orbital period at R_{Alf} , $t \approx 2\pi(GM/R_{\text{Alf}}^3)^{1/2} \approx 1$ s (ref. 10), as observed. This model, like the standard

model, cannot easily account for reported asymmetries in the pulse profile.

I thank Drs W. Tucker, R. B. Partridge, and L. C. Green for discussions and Dr R. Giacconi for giving his time and making this work possible.

Cosmological effects of primordial black holes

ALTHOUGH only black holes with masses $\gtrsim 1.5 M_{\odot}$ are expected to result from stellar evolution¹, black holes with much smaller masses may be present throughout the Universe². These small black holes are the result of density fluctuations in the very early Universe. Density fluctuations on very large mass scales were certainly present in the early universe as is evident from the irregular distribution of galaxies in the sky³. Evidence of density fluctuations on scales smaller than the size of galaxies is generally thought to have been destroyed during the era of radiation recombination⁴. But fluctuations in the metric of order unity may be fossilised in the form of black holes. Observation of black holes, particularly those with masses $M < M_{\odot}$, could thus provide information concerning conditions in the very early Universe.

One indication that many black holes exist at present in the Universe is the evidence that the average density of matter in the Universe greatly exceeds the observed density of matter. Application of the virial theorem to galactic clusters⁵ implies that the density of matter is at least five times the observed density. Measurements of the deceleration⁶ and positions³ of galaxies suggest that the density of matter may be larger than the observed density by a factor ~ 100 —perhaps enough to make the Universe closed, although these measurements are rather uncertain. On the other hand, there are reasons⁷ for believing that the observed deuterium in the Universe was formed in the early radiation era. This would place an upper limit on the free nucleon density during the first 15 min of the Universe. This upper limit on the nucleon density implies that the present-day matter density $\lesssim 6 \times 10^{-31} \text{ cm}^{-3}$, that is, ~ 10 times the observable matter density. This upper limit on the total matter density would be consistent with applications of the virial theorem to galactic clusters but would not be consistent with the above-mentioned measurements suggesting a higher density. If evidence for a cosmologically flat or closed Universe holds up then it follows that during the first 15 min most of the matter in the universe must have existed in some other form than free nucleons—in other words, black holes.

If many small black holes ($M < M_{\odot}$) exist at the present time then their presence may be revealed because they radiate electromagnetic radiation. Indeed, during collapse the metric will be changing rapidly on a time scale $\tau \approx 10^{-5} (M/M_{\odot})$ so that production of massless particles with energy of order h/τ is expected⁸. Thus masses smaller than about 10^{20} g will radiate X rays and gamma rays when they undergo gravitational collapse. Hawking⁹ has suggested that the emission of massless

particles can be interpreted by saying that black holes have a temperature $\sim 10^{-6} (M_{\odot}/M)$ K. This interpretation implies that black holes with masses as large as 10^{15} g would have radiated away all their mass by now. Davies and Taylor¹⁰ have, however, suggested that the emission of radiation from a black hole only takes place for a brief instant during the collapse and that only black holes with mass $\lesssim 10^{-4}$ g will radiate away a significant fraction of their mass. If they are correct then practically all radiation due to black holes would have been emitted in the very early Universe and at the present time would only show up as a possible contribution to the 3 K microwave background.

On the other hand, if Hawking's interpretation is correct then small black holes would have produced X- and gamma-radiation up to and including the present time. If the black hole mass spectrum is not varying too rapidly the result would be background radiation the spectrum of which started out as a continuation of the 3 K blackbody spectrum and rose slowly to a peak at an energy determined by the smallest black hole mass now existing. Observational evidence for Hawking's interpretation might be provided by a distortion in the 3 K blackbody spectrum for wavelengths < 1 cm or by a peak in the isotropic X-ray background above 10 MeV (corresponding to Hawking's estimate of 10^{15} g as the smallest black hole mass now existing). A flattening of the isotropic X-ray background spectrum at about 30 MeV has, in fact, been reported¹¹. If we identify the measured X-ray flux associated with this feature ($\sim 10^{-6}$ photons $\text{cm}^{-2} \text{s}^{-1} \text{keV}^{-1}$) with X-ray emission from black holes with masses in the neighbourhood of 10^{15} g then one arrives at a space density of these black holes $N_{\text{max}} \approx 10^{-52} \text{cm}^{-3}$. Because the present-day spatial density of galaxies is about 10^{-76}cm^{-3} we conclude that there may be as many as 10^{23} small black holes per galaxy. If we assume that the volume of our Galaxy is 10^{12}pc^3 then a region the size of our Solar System ($\sim 10^{44} \text{cm}^3$) might contain several small black holes. Of course, there are other possible interpretations^{12,13} of the 30 MeV feature in the X-ray background and therefore the actual spatial density of small black holes may be much less than N_{max} .

In order to calculate the contribution of small black holes to the total mass of the Universe one must make some assumption about the primordial black hole mass spectrum. The simplest assumption that can be made is that the number of black holes in each logarithmic interval of mass is the same

$$dN = N_0 dM/M \quad (1)$$

This assumption is consistent with the idea¹⁴ that perturbations of the metric in the early Universe should be independent of scale length.

With the mass spectrum (1) the total mass of primordial black holes is $N_0 M_{\text{max}}$ where M_{max} is the maximum mass of a primordial black hole. Taking $N_0 = N_{\text{max}}$ and a present-day mass density $\lesssim 10^{-30} \text{g cm}^{-3}$ gives $M_{\text{max}} \lesssim 10^{22} \text{g}$. This maximum mass for primordial black holes may be related to the Hubble mass at the time when black hole formation in the early Universe stopped. It is interesting that the Hubble mass was equal to 10^{22}g at some time during the hadron era ($t < 10^{-4} \text{s}$) when large density fluctuations are 'predicted' to occur in some theories of dense hadronic matter¹⁵. Conversely, identification of any of the cosmological effects we have discussed as being the result of small black holes should provide some information on the nature of dense hot hadronic matter. A search for evidence of small black holes in the Solar System might be very worthwhile. Indeed, the existence of small black holes in the Solar System might have considerable economic significance because small black holes would be very useful as power sources¹⁶.

ATS-6 radio beacon experiment

SINCE ATS-6 was launched into a geostationary orbit at 94°W in late May 1974, measurements of the total electron content (TEC) using the Faraday polarisation-rotation¹ and group dispersive-delay techniques have been made at Fort Monmouth (40°18'N, 74°06'W). Comparison of TEC rate of change obtained by the two techniques yields the temporal variation of the integrated number of free electrons above the ionosphere. This variation indicates a flow of electrons from regions above the ionosphere into the ionosphere at night, while during the day the direction of flow is reversed. The rate of the electron flux is estimated using the continuity equation.

The total Faraday¹ rotation from the signal source to the observer is related to the total electron content by the expression

$$\begin{aligned} a &= (k/f^2) \int B \cos \theta N ds \\ &= (k/f^2) \int (B \cos \theta \sec \chi) N dh \\ &= (k/f^2) M N_1 \end{aligned} \quad (1)$$

where $k = 2.36 \times 10^{-5}$, M is the magnetic field factor (at 420 km), N_1 is the total ionospheric electron content, and $f = 140$ MHz. As B decreases inversely with the cube of the geocentric distance and the electron density decreases exponentially with altitude above F_2 (max) (~ 300 km), the rotation is heavily weighted near the Earth and is considered to provide electron content values below $\sim 1,200$ km.

Using the dispersive-group-delay technique², the phase of the modulation envelope between a carrier and its sideband is compared at two frequencies (nominally $f_{1,2} = 140, 360$ MHz with a sideband displacement of $\Delta f = 1$ MHz). Since the phase is insensitive to the Earth's magnetic field, this technique yields the number of electrons along the entire path from satellite to observer (N_T).

The differential modulation phase $\Delta\phi$, in degrees, is

$$\Delta\phi/360 = 40.3 \Delta f/c \sec \chi (f_1^{-2} - f_2^{-2}) N_T \quad (2)$$

where c is the speed of light *in vacuo*, and χ is the zenith angle.

The relative variation of the total electron content measured by the Faraday and group-delay techniques is shown in Fig. 1a and b at 15-min intervals for the time period 1600 EDT on July 3 to 0800 EDT on July 8. The temporal variations of N_1 and N_T were nearly parallel with most density variations observed on both curves. In general, $\Delta N_1/\Delta t$ and $\Delta N_T/\Delta t$ varied between $\pm 1 \times 10^{16}$ electrons m^{-2} per 15-min interval.

Large increases of total electron content, in response to two large solar flares, are prominent during the time period covered by Fig. 1. Between 0945 EDT and 1000 EDT on July 4, N_1 increased by $\sim 1.5 \times 10^{16}$ electrons m^{-2} , while N_T increased by $\sim 2 \times 10^{16}$ electrons m^{-2} . Since the content values in Fig. 1a and b are given every 15 min, the full increase of N_1 and N_T is not indicated there. Starting at ~ 0953 EDT, N_1 increased by $\sim 3.3 \times 10^{16}$ electrons m^{-2} in 3 min and then decayed to its figure value at 1000 EDT. At the same time, N_T increased by approximately

the same amount. On July 5 between 1730 and 1745 EDT, N_I increased by $\sim 1.9 \times 10^{18}$, while N_T increased by $\sim 2.3 \times 10^{18}$. The rapid increases started at ~ 1740 EDT with N_I increasing by $\sim 2.1 \times 10^{18}$ in ~ 6 min, N_T increased similarly.

The dispersive-group-delay technique measures the total electron content from observer to the geostationary satellite, whereas the Faraday technique yields the content only in the vicinity of the Earth (up to $\sim 1,200$ km). The difference between the two yields is the content above $\sim 1,200$ km, which is referred to as the plasmaspheric content, N_P .

It follows that the rate of change of the plasmaspheric content is

$$\Delta N_P / \Delta t = \Delta N_T / \Delta t - \Delta N_I / \Delta t \quad (3)$$

The rate of change $\Delta N_P / \Delta t$ at 15-min intervals is plotted in Fig 2a and b for the same time period as Fig 1. The absolute values of $|\Delta N_T / \Delta t| - |\Delta N_I / \Delta t|$ for either positive (N_I and N_T both increase) or negative (N_I and N_T both decrease) are indicated. A negative value for either of the two cases indicates that the N_I variations was larger than the N_T variation. This must indicate a flow of electrons between the plasmasphere and the ionosphere, which would change N_T by a lesser amount than the corresponding change in N_I .

Figure 2 shows that, for the most part, the changes of the plasmaspheric content at 15-min intervals were generally restricted to $\pm 0.5 \times 10^{18}$ electrons m^{-2} .

As expected the rate of change of N_T was more often than not larger than the rate of change of N_I (all positive values in Fig 2). We expect this because N_I is part of N_T , and any changes in N_I will be reflected in N_T . An interesting behaviour of $\Delta N_P / \Delta t$ occurred during the decay phase of the content on July 5-6, July 6-7 between ~ 2000 and 0430 EDT, when it was generally positive indicating that the total content was decreasing faster than the ionospheric content. Since loss of plasmaspheric content through recombination cannot account for the difference between $\Delta N_T / \Delta t$ and $\Delta N_I / \Delta t$, the only plausible

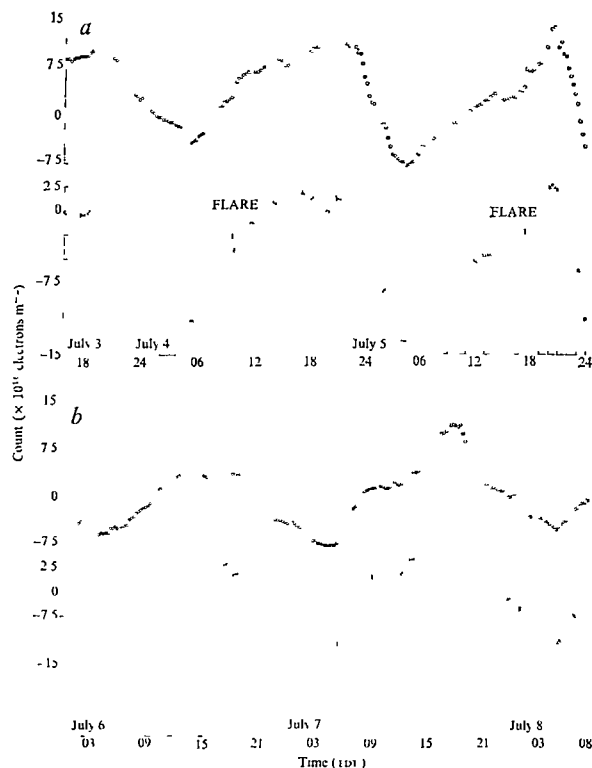

Fig 1 Relative variation of total electron content, N_T (○), and ionospheric electron content, N_I (×) at 15-min intervals 1600 EDT, July 3, 1974, to 0800 EDT, July 8, 1974, at Fort Monmouth, New Jersey

Fig 2 Variation of plasmaspheric electron content ($N_T - N_I$) ○, variation for $N_T, N_I > 0$, × variation for $N_T, N_I < 0$ A negative value indicates $N_I > N_T$

cause for the difference is electron flux from the plasmasphere to the ionosphere.

I suggest the following mechanism. The ionospheric electron content decreased sharply which resulted in equal decreases of N_T and N_I . With the corresponding fall in electron temperature, ionospheric layer collapse induced electron fluxes from the plasmasphere to the ionosphere. Although these fluxes did not alter the value of N_T , since they were still measured by the group delay technique, they did slow the rate of decrease of N_I because they reached lower altitudes where they were then measured by the Faraday rotation technique. Increases in total ionospheric electrons³⁻⁵ can be seen with the Faraday technique only when the flux rate exceeds the recombination rate, indicating an actual increase in ionospheric total density. But with the combination of Faraday and group-delay techniques, made possible by the radio beacon experiments of ATS-6, such fluxes may be determined even when their rate is smaller than the decay rate due to recombinations.

Assuming electron transport in the vertical direction only, the magnitude of the fluxes can be estimated.

The rate of change of N_I can be expressed by the continuity equation

$$\Delta N_I / \Delta t = q_I - L_I - F \quad (4)$$

where q is the production rate, L is the loss rate ($L = \int_{\text{Ionos}} \beta(h) N(h) dh$ where $\beta(h)$ is the loss rate coefficient) and F is the flux term. Similarly for N_T

$$\Delta N_T / \Delta t = q_T - L_T \quad (5)$$

The flux term has been omitted here since any fluxes between ionosphere and plasmasphere will still be measured by the group-delay method. Since production and loss are effective only at ionospheric heights, it follows that $q_T \approx q_I$, $L_T \approx L_I$, and therefore

$$\Delta N_T / \Delta t - \Delta N_I / \Delta t \approx F \quad (6)$$

using the results of Fig 2, the estimated fluxes are $\lesssim \pm 10.5 \times 10^{13}$ electrons $m^{-2} s^{-1}$.

Particle fluxes also play a role during the build-up phase. For example, between 0400 and 1400 EDT on July 6, $\Delta N_P / \Delta t$ was generally positive indicating that N_T increased faster than N_I . Electron production cannot contribute to an increase in N_P , but an increase in the particle temperature expands the ionospheric layers and thus causes electron fluxes from the ionosphere to the plasmasphere, increasing the content of the latter N_T .

reflects the increase in production in the ionosphere and electrons in the plasmasphere due to these fluxes. The rate of increase of N_1 is slower since the fluxes slow down the rate of increase by electron production.

I thank Mr J A Klobuchar of AFCRL for supplying the M factor, and Mr F J Gorman who supervised the collection of data.

Effect of vorticity pollution by motor vehicles on tornadoes

THE recorded annual incidence of tornadoes in the United States has increased steadily and dramatically in the past four decades, by at least a factor of six¹. We have examined the thesis that the development of widespread motor vehicle traffic in the United States over the last 40 yr has perturbed atmospheric vorticity in such a way as to exacerbate the tornado incidence, principally by the introduction of cyclonic vorticity. Surprisingly, both the analysis and the evidence support the thesis.

Tornadoes depend on non-random vorticity in strong convection and motor vehicle traffic produces a unique anthropogenic input of non-random vorticity into the troposphere.

Motor traffic on the North American continent passes opposing traffic on the right. The thrust of each motor vehicle against the solid Earth is thus ordinarily to the right of that of the opposing traffic. To the extent that these thrusts result from momentum transfer to the atmosphere, a plethora of additive anticyclonic force couples act on the Earth's crust, and cyclonic torque is applied to the atmosphere. These effects persist and accumulate, limited only by the exchange of the atmospheric vorticity with the solid Earth, which according to our calculations occurs slowly. It is this anthropogenic addition to atmospheric cyclonic vorticity that might constitute a link between motor vehicle traffic and tornadoes. We are here neither contemplating the temporary turbulence in the wake of passing vehicles, nor the angular momentum stored in the vehicles underway, but rather the interaction of the opposed atmospheric momentum streams engendered by two opposed streams of traffic (Fig 1).

In the USA there are $\sim 2 \times 10^6$ automobiles and 6×10^5 trucks underway at any average moment². Cyclonic vorticity introduced into the troposphere by US traffic in one week is much greater than the Earth's vorticity, and annually is of the order of 10^5 – 10^6 times the vorticity involved instantaneously in a single tornado. Trucks and automobiles contribute equally. In our calculation we used an average spacing of 20 m between opposed traffic streams. The magnitude of the torque is of course dependent on this number, and recent increased spacing between lanes has increased the total torque, but a reasonable range of spacings would affect the torque by less than one order of magnitude.

In our model, the continent was initially enveloped in a tropospheric air mass, drifting west to east, that contained an overall cyclonic vorticity with substantial regions of no or anticyclonic vorticity. With the increase of motor vehicle traffic, the air masses were treated with increasing cyclonic vorticity, which cancelled much of the anticyclonic vorticity and produced (a), a more homogeneously cyclonic troposphere, (b), more numerous (and more dominantly

Fig. 1 "For they have sown the wind, and they shall reap the whirlwind" Hosea 8:7. The cyclonic vorticity introduced into the atmosphere is generated by the torque between the two opposing streams of traffic. The smaller side vorticities created at the periphery of the highway are boundary effects eventually acting at large distances (perhaps finally at the antipodes, where they are also cyclonic).

cyclonic) tornadoes, (c), a migration of the "centre" of tornado intensity to the east, and (d) secular and periodic variations of tornado incidence reflecting major changes in motor vehicle traffic (for example, weekly). The records indicate that these phenomena have occurred.

We have obtained the detailed record of all US tornadoes (15,234) reported between 1950 and 1873 in the 48 contiguous states³. The annual incidence shows an increase over the period of a factor of four. Changes in observation and reporting are undoubtedly serious and we have applied tests that are relatively independent of secular changes in reporting.

The annual centre of tornado intensity weighted by the area of each tornado path has varied considerably and has increasingly occupied the eastern portion of the continent in the second half of the record, as our thesis predicts.

Pollution by cyclonic vorticity should have lowered the relative incidence of anticyclonic tornadoes, and this has occurred. In the first half of the record (1950–61) 4 out of 11 events for which sense was recorded were anticyclonic, whereas in the second half, this was true for only 10 out of 123. A random selection of 11 events from a distribution similar to that of the second time period would have approximately a 7.5×10^{-3} chance of recording four or more anticyclonic tornadoes.

The data display a strong weekly periodicity.

Over the entire record the reported number of tornadoes on Saturdays is less than the daily average by more than 7.1 standard deviations (1,868 on Saturdays as against a daily average of 2,176). The statistical probability of this record occurring by chance from a random sample is $P < 10^{-8}$. This hebdomadal event dominates in 18 of the 24 yr and in most

states (Thirty-seven of the forty-eight states show a Saturday incidence below the average, $P \sim 10^{-4}$). Nineteen states show Saturdays incidence to be a minimum ($P = 1.5 \times 10^{-3}$).

We attribute this weekly periodicity to the periodicity of vorticity introduction by motor vehicle traffic. We attribute the general Saturday minimum to the fact that most truck and commuter traffic ceases on a Friday, and to the unidirectional character of the weekend flow, both in and out of urban areas, which probably introduces mainly a momentum stream into the atmosphere on Saturdays, generating net cyclonic vorticity later and downwind by interaction with the momentum stream of the traffic returning on Sunday. Other effects such as a weekend diminution of heat or particle production by industry and motor vehicles or of the efficiency of reporting are difficult to reconcile with average tornado incidence on Sundays in most states.

We would expect the strongest hebdomadal fluctuations to occur in states dominated by fresh, relatively unsullied oceanic air masses and thus influenced more sharply by the immediate input of vorticity. Indeed, coastal states display an enhanced weekly cycle with 12 of the 21 coastal states showing the Saturday incidence of tornadoes to be a minimum, and 19 of the 21 showing Saturdays to be below average in tornado occurrence (as opposed to seven showing Saturday minima and 18 showing Saturdays below average in the 27 interior states). These statistics for the special class of coastal states have 0.04 probability of being a chance selection from the statistics of all states. This test of our thesis should be independent of general reporting peculiarities, and so is crucial evidence in its support.

Additionally, as the thesis predicts, far western coastal states display a special selection of the statistics of all coastal states with minima for both Saturdays and Sundays. No far western state is subject to many tornadoes (also perhaps in support of our thesis) and, in the extreme case of the state of Washington, of the 25 tornadoes reported in the past 24 yr, none occurred on Saturday or Sunday ($P \sim 2.2 \times 10^{-4}$).

Vorticity is a unique requirement for the formation of tornadoes and hurricanes, and motor vehicles are the only man-made source of non-random vorticity we know. From our initial findings we provisionally assign an increase in reported US tornadoes to vorticity pollution by motor vehicles. If this is the case, mankind, excluding mainly the British, may need to take responsibility for yet another deleterious environmental effect. But vorticity pollution could be turned to benefit. If the obvious turnabout were made, there might well be an immediate and secular decrease in tornadoes, perhaps to levels below the natural intensity, duration and frequency.

Regardless of the veracity of our thesis, some anthropogenic effect clearly has resulted in about 300 fewer tornadoes reported in the US on Saturdays than on other days of the week, in the past 24 yr. If this results from the reduction of some human activity on Saturday (other than tornado reporting), then at least 14% of US tornadoes are under man's control. The total of man's effects could, of course, be much larger since an accumulating diffuse reservoir of vorticity might account for more of the long term (600%) increase in tornado incidence (or even changes in hurricane incidence, path and intensity) in the Northern Hemisphere.

Diachronism of depositional and diastrophic events

ONE of the fundamental principles of geology—'Stille's legacy'¹—is the concept that there is a wide contemporaneity of geological events, both tectonic and sedimentary. The concept received notable attention 25 yr ago and raised a scientific controversy². It is now of interest again because of the present tendency to assume as a causal mechanism of mountain building the relative motions between plates. On the basis of geological evidence it has been shown³ that the diastrophic events of the western Mediterranean do not occur at the same time in the different mountain chains, because collisions between plates are diachronous. Detailed stratigraphical analysis of the units within the Maghrebian Chain⁴ (from Gibraltar to Calabrian Arc) indicates that, in addition, the initiation of geological events varies from place to place in the same orogen⁵.

The Maghrebian Fold Belt was produced largely by the tectonic deformation of three groups of Oligo-Miocene flysch (the 'tectonic triad of flysch types'⁵) (see Fig. 1).

One group is represented by a Nile Cone-type^{5,6} 'passive margin' sequence which terminates in the upper part with an alternation of quartz-rich sandstones and iron-rich silty clays. In Sicily these African-derived⁷ miogeoclinal quartzose deposits derived from Africa, comprise typical submarine fan facies (the 'external' Nubian Flysch and the 'internal' Numidian Flysch) and abyssal plain facies (the Malia Flysch). The basal strata of these units are transgressive northwards over multicoloured marls (scaglia-type formation⁸) and clays (*Argille varicolori*⁵) interpreted as deep-water basinal facies. The northward fan progradation occurred with a biostratigraphically estimated rate of about 10–20 km Myr⁻¹ (Fig. 2).

The second contemporaneous flysch group (Hellenic Trench-type suite^{5,6}) comprises marly-arenaceous, compositionally-immature turbidites (Tusa Flysch). The marls are homogeneous ('homogenites') and probably originate from ponding by turbidity currents^{5,6}. The sandstones are lithic (clastics from granitic-metamorphic and sedimentary sources) with sometimes significant andesitic components⁸. The Tusa Flysch sequences constitute successive thrust sheets, each sheet less than 800 m thick and progressively younger southwards. This tectonic juxtaposition is inferred to be the result of subduction under the Calabrian Massif of original trench-filling sediments^{3,5}. Migration of the trench axis occurred at only about a fifth of the rate of progradation of the Nile Cone-type flysch (Fig. 2).

The third member of the 'triad' (the Crete Basin-type flysch⁵) is a thick, tectonically undeformed, arenaceous sequence which is transgressive on the Calabrian Massif in the internal (northern) zones and overlies the tectonically deformed Tusa trench-fill deposits in the external (southern) zones. This neo-autochthonous sedimentation (Reitano-Capo d'Orlando Flysch) is believed to be an arc-trench gap accumulation⁸ that advanced progressively southwards over the deformed trench deposits accreted to the front of the Calabria microplate^{3,5}. Sicilian

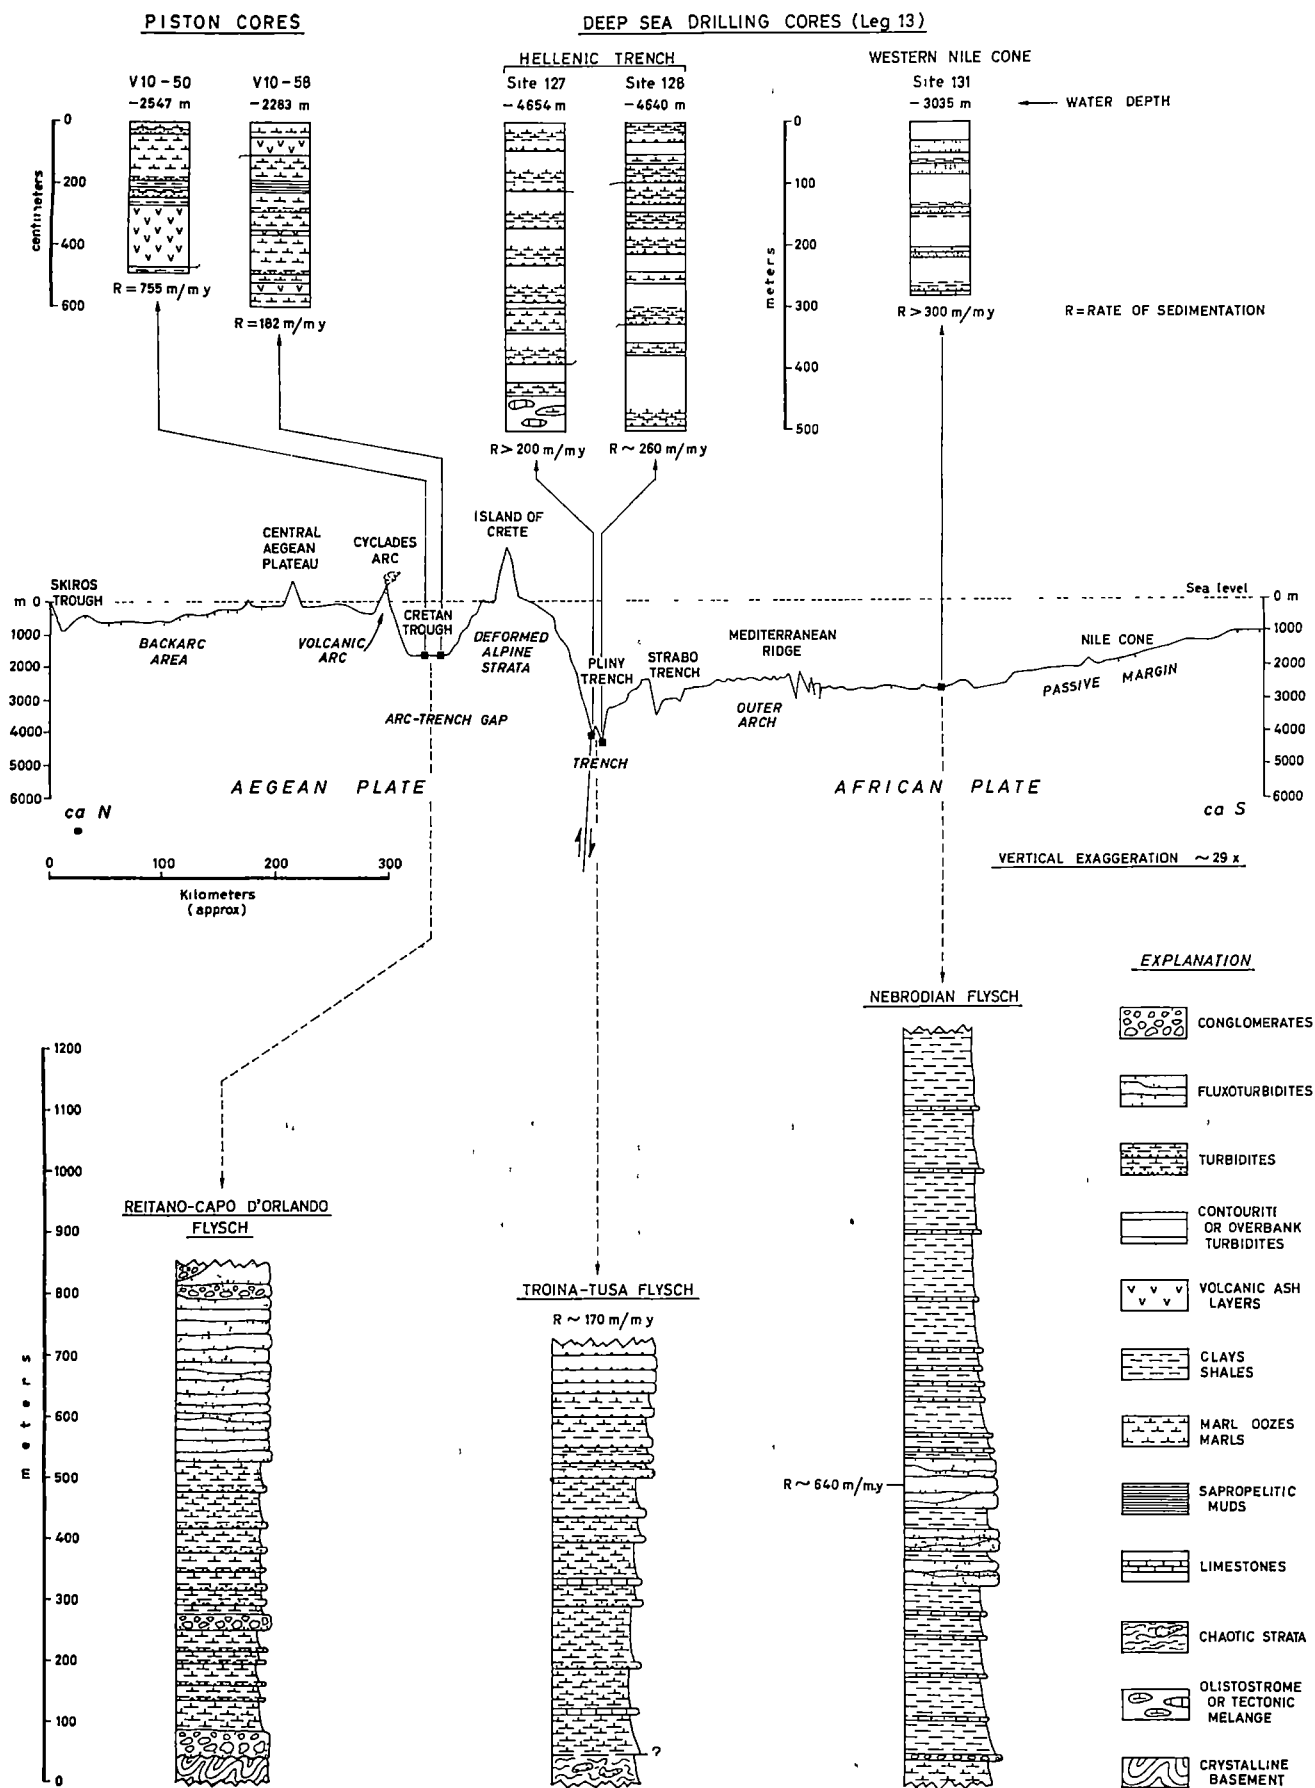

Fig. 1 The 'tectonic triad of flysch types' characteristic of a contracting basin, showing the present day (factual) and the ancient (inferred) tectonic settings for the three litho tectonic assemblages. In the upper part, the Quaternary sedimentary columns of the JOIDES cores⁶ and two Vema piston cores¹² were projected on to a bathymetric profile crossing the eastern Mediterranean and the southern Aegean at approximately 25°E¹³. The lower part shows generalised columnar sections of the three equivalent Oligo-Miocene flysch groups which crop out in the Sicilian part of the Maghrebain Chain.

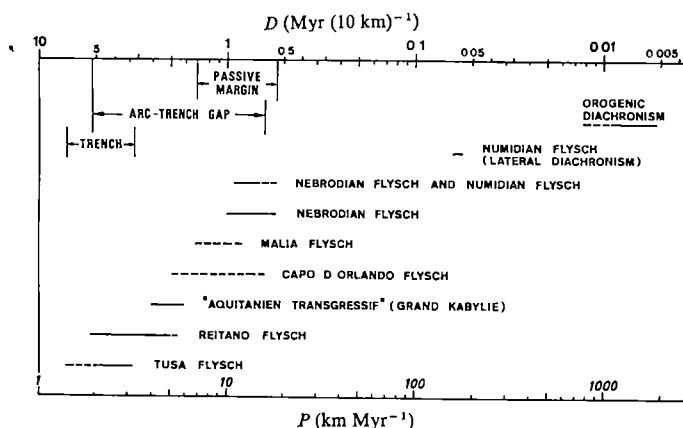

Fig 2 Biostratigraphic estimates of the transgression of basal strata of the Oligo-Miocene flysch and of orogenesis in Sicily. Depositional events—trench (Tusa Flysch) and arc-trench gap sedimentation (Reitano-Capo d'Orlando Flysch)—are characterised by a greater diachronism than passive margin deposition (Nebrobian, Numidian and Malia Flysch). The migration of the crustal suturing along the Maghrebain Chain is near the boundary of the time resolution at present achieved with planktonic foraminiferal zonation P , the rate of progression in km Myr^{-1} , and D , the diachronism coefficient in Myr (10 km)^{-1} , are new parameters proposed⁶ for a better quantitative evaluation of the magnitude of diachronism. Using these parameters 'bio-isochron lines' can be traced on geological maps, allowing estimations of relative past positions of passive and active continental margins.

data indicate a time span of only 3–4 Myr for a single 'tectogenetic cycle' which includes syntectogenetic trench sedimentation, tectonic deformation and the beginning of deposition of the arc-trench gap cover. In northern Morocco, between Tangiers and Ceuta, there is a spectacular juxtaposition of successive elongate thrust belts comprising Hellenic Trench-type flysch (Beni-Ider) and Numidian Flysch, and probably caused by the progressive accretion of deposits deformed in eastward facing subduction zones (F. Guerrero and W. B. F. Ryan, personal communication).

As in the case of the depositional events, the timing of orogeny is not synchronous everywhere in the Maghrebain Chain. Collision and suturing of the northern microplates and the North African continental margin occurred about 1 Myr earlier in Algeria¹⁰ (late Burdigalian) than in Sicily⁵ (early Langhian). The eastward migration of the locus of collision was accompanied by the termination of Numidian deposition. The most likely reason for this diachronous orogenesis seems to be either a non-parallelism between the approaching continental margins or an oblique closing of the flysch basin with some component of transcurrent motion.

In view of these data it seems difficult to maintain the classical concept that the Maghrebain nappes originated primarily as a result of centrifugal gravitational sliding away from an uplifted Tyrrhenian zone¹¹. The noncontemporaneity of sedimentary and diastrophic events in different parts of the same orogenic belt also brings into question the validity of the rigid formalism of traditional (proto) stratigraphical philosophy (that is, the platonic idea of stratotypes). It seems that a dynamic (sedimentological-ecological) approach would be more appropriate.

Efficiencies of electrolytic and thermochemical hydrogen production

Two methods not involving fossil fuels for manufacturing hydrogen have been suggested as a basis for an eventual hydrogen economy: first, electrolysis of water using nuclear (or ultimately solar, geothermal or thermonuclear) electricity and, second, thermochemical cycles using nuclear heat, in general from a high temperature reactor^{2,3}. In the thermochemical processes, a series of chemical steps is envisaged that will allow the differential splitting of the H_2O molecule by means of reactions at different temperatures and with appropriate thermodynamic requirements to give high efficiency. The sequence of reactions, ideally of gas-solid type, acts as an adsorption-desorption-cycle heat engine. For economical hydrogen production, high thermal efficiency combined with low capital investment cost is necessary. The question is whether a system constructed on the basis of a sequence of chemical reactions will be more efficient (and ultimately less costly) than one based on a heat engine producing electricity, followed by electrolysis. Here I shall examine briefly some aspects of the efficiency of both approaches.

In the electrochemical case, the overall thermal efficiency is relatively simply defined as

$$e_t = \Delta H^0 / Q \quad (1)$$

where ΔH^0 is the standard heat of reaction for the oxidation of hydrogen to water under the conditions of use and Q is the total quantity of heat needed to effect the breakdown of 1 mol of water. If the electrolysis is reversible, that is, if the electrode processes (under conditions of no net reaction) with the reactants and products in their standard states have an exchange rate that is much higher than the desired net rate of breakdown, then, Q will be given by

$$Q = x\Delta G_t^0 + T\Delta S_t^0 \\ = x\Delta G_t^0 + (\Delta H_t^0 - \Delta G_t^0) \quad (2)$$

where ΔG_t^0 , ΔH_t^0 and ΔS_t^0 are the standard free energy, heat of formation and entropy of water at the temperature of electrolysis and x is the factor for the conversion of heat into (electrical) work. In general, liquid water will be used as feed-stock, therefore the ΔG_t^0 and ΔH_t^0 terms in Q will be those for liquid water. By contrast, the ΔH^0 term may be either for gaseous or liquid water, depending on whether or not condensation takes place during use of the heat.

In a real electrolyser, three types of loss occur, all of which add ΔG terms. The first results from the fact that the reactions at the electrodes have finite rates (overpotential). This is particularly so for the case of the oxygen electrode at normal temperatures. This overpotential is given by the Butler-Volmer equation in the most general case. The equation must, however,

be modified to take account of the effects of changing effective electrode area and of changing reactant concentration, which result from the remaining two losses—current distribution stemming from local resistance, and reactant depletion because of mass-transport effects (for example, the formation of product gas bubbles). In addition, irreversible energy loss occurs because of resistive (IR) drop throughout the system. Altogether, the additional free energy that must be provided to decompose water is conventionally represented by

$$\Delta(\Delta G_t) = \Delta G_\eta + \Delta G_{diff} + \Delta G_{IR} \quad (3)$$

where ΔG_η is the overpotential, calculated from the ratio of the net and exchange (equilibrium) rates of reaction using the Butler–Volmer equation, assuming the whole surface of the electrode to be active, ΔG_{diff} is the effective diffusion loss, and ΔG_{IR} is the loss attributable to the IR drop. For relatively small displacements from equilibrium, the ΔG_η and ΔG_{diff} terms linearise, so that the combined $\Delta(\Delta G)$ term is of pseudo-ohmic type. An expression for an uncomplicated single-electrode process under these conditions is given by

$$\Delta(\Delta G_t) = \iota \left[RT \left(\sum_n \frac{1}{\iota_{0j}} + \sum_m \left| \frac{1}{\iota_{Dk}} \right| \right) + nFR' \right] \quad (4)$$

where ι is the rate of decomposition (current per unit area), R is the gas constant, ι_{0j} is the equilibrium reaction rate of the j th reaction step, ι_{Dk} is the diffusion-limited rate of the k th step, and R' is the internal electrical resistance per unit area. In general only one step in each case will predominate with regard to diffusional and kinetic limitations, however, if the limiting steps occur more than once in the overall process, the $1/\iota$ terms must be correspondingly summed over the number of times they occur.

In general, for electrolysis at low temperatures $\Delta G_t^0 + \Delta(\Delta G_t)$ will exceed ΔH_t^0 , since under these conditions kinetic and diffusional limitations are considerable and, in any case, the value of $\Delta H_t^0 - \Delta G_t^0$ is small (~ 12 kcalorie for liquid water at ambient temperature). All the energy required for water decomposition will thus be free energy in the form of electricity. At higher temperatures, ΔG_t^0 falls rapidly (ΔG_t^0 for water vapour ~ 44 kcalorie mol^{-1} at 700°C) and the kinetic and diffusional terms become less important, so that in principle only a part of the energy used need be electrical work, the rest being provided by heat.

For the thermal method of splitting water, which involves the use of a series of chemical cycles devised in such a way that the ΔG^0 in each reaction is close to zero, thermal efficiencies are much less easy to define in detail. In general, if one assumes a perfect system with infinitely rapid reactions (complete reversibility) with no heat losses, then the efficiency is given by an expression similar to equation (1), summed over all the n reaction steps to be used in the cycle, that is

$$e = \Delta H^0 / Q_{rev} = \Delta H^0 / [x \sum_n \Delta G_{t,j}^0 + \sum_n (\Delta H_{t,j}^0 - \Delta G_{t,j}^0)] \quad (5)$$

where the j e terms refer to the j th step⁴. If the reactions involve separations, particularly of gaseous components, an irreversible work of separation corresponding to $T\Delta S_m$, where ΔS_m is the entropy of mixing of the components, must be added to Q_{rev} (ref. 4). This is, of course, directly avoided in electrolyte procedures. For this reason, cycles with gas–solid reactions involving only one gas are to be preferred where possible. In addition, inevitable heat losses that cannot be partially used as work will occur in the processes. Hence Q is given by

$$Q_{rev} + x \sum T \Delta S_m + \text{heat losses}$$

So far in the literature, efficiencies for the thermal cycle

method of generating hydrogen have been calculated on the above basis. In several cases (see ref. 5) x , the factor for the conversion of heat into work, has even been ignored (see, however, refs 4 and 6).

All such calculations regard the processes as ideal—each step is not only at equilibrium but is infinitely rapid compared with the net rate of the reaction. This situation is obviously idealised and corresponds precisely to ignoring the overpotential factors in electrolysis. As in the latter, free energy losses occur because of the net rate of the processes resulting from three similar causes: kinetic, diffusional and frictional. The kinetic limitations of each step are given by the chemical equivalent of the Butler–Volmer equation, namely the Marcelin–De Donder equation⁷. This may be expressed in the form

$$k = k_0 [\exp(\Delta A / RT) - (\Delta A' / RT)] \quad (6)$$

where k is the net rate of the process, k_0 is the equilibrium rate and ΔA , $\Delta A'$ are the displacements of chemical potential of the reactants and products from equilibrium (affinities) corresponding to overpotential in the electrochemical case.

In general, the reactions chosen for thermochemical cycles will be, in the optimum case, solid–gas reactions, in which the chemical potential of the reactants may be taken to be independent of the amount of material reacted. In these conditions, the measured (out of equilibrium) rate of reaction, on which process scaling is based, will be of the same order as that for the equilibrium rate. For a net rate close to this value, the minimum value of ΔA will be of the order of $1.3RT$ for each separate reaction step. Summed over all steps for a four-step process at an average temperature of 800 K , this represents 8.3 kcalorie of pumping work. Taking into account the x factor and system inefficiencies (viscous losses, concentration gradients), the total extra energy input may amount to 30 kcalorie per mol hydrogen as a reasonable minimum. Similar considerations apply to diffusion-limited steps, whether they occur in the chemical steps or in component separation. The latter will introduce additional work terms that must be added to the separation work. This extra energy can present a serious additional fall in overall efficiency. For example, a process with a reported estimated efficiency (hydrogen low heating value) of 45% (ref. 6), after all reversible work and heat losses are accounted for, will have a real maximum efficiency of only about 36% if one considers only the irreversible losses in the chemical steps. If the irreversible losses in separation steps are considered, the estimated maximum efficiency may approach 30% . This point illustrates the fact that irreversible thermodynamic considerations cannot be ignored in calculating the efficiencies of thermochemical cycles in which affinities must be summed over several steps, giving typical requirements for total extra work which may be greater than those for separation work. It seems, in fact, that, when all factors are taken into account, processes based on thermochemical conversion may prove to be less efficient than projected electrolyzers, both processes being supplied from a heat source at the same temperature.

Enhancement in thermonuclear reaction rates in a dense plasma

For laser-driven fusion, a number density of the order 10^{26} cm^{-3} is usually envisaged^{1,2}, here I consider the effects of the presence of a medium on the nuclear reaction rates³ and show the feasibility of enhanced fusion rates when a certain condition is met. The results are applicable both to controlled thermonuclear reactions and to astrophysical conditions.

For a head-on collision of two particles carrying charges $Z_1 e$ and $Z_2 e$ in an electron-ion plasma with dielectric constant $\epsilon(\mathbf{k}, \omega)$, the Coulomb interaction is modified to⁴

$$V(\rho) = (4\pi Z_1 Z_2 e^2 / \nu) (2\pi)^{-3} \int d^3 \mathbf{k}_\perp \int_{-\infty}^{\infty} d\omega \times \\ \{ [k^2 \epsilon^2(\mathbf{k}, \omega)]_{k_z = \omega/\nu} \}^{-1} \exp \{ i(\omega \rho / \nu) \} \quad (1)$$

($Z_1 = Z_2 = 1$ for a deuterium-tritium (DT) mixture) Here, ν is the velocity of the incident particle which is taken to be along the z direction $\mathbf{k} = (k_\perp, k_z)$, and $\rho = z - \nu t$ is the distance between two colliding particles.

The ion velocity ν of interest usually far exceeds the ion thermal velocity $\nu_T = (3k_B T / M)^{1/2}$, where T is the ion temperature and M is the ion mass (For a DT mixture, M is taken to be a suitably averaged ion mass) Furthermore, when the electron temperature T_e exceeds T so that $\nu \ll u_T$ (where $u_T = (3k_B T_e / m)^{1/2}$ is the electron thermal velocity), we have

$$\epsilon(\mathbf{k}, \omega) \simeq (k_D / k)^2 + \{ 1 - [\Omega_p / (\omega + i\delta)]^2 \} \quad (2)$$

where $\delta \rightarrow 0+$, $k_D = (4\pi n_e e^2 / k_B T_e)^{1/2}$, and $\Omega_p = (4\pi n_e e^2 / M)^{1/2}$. (n_e is the number density of the electrons) For $(k_D \rho)^2 \ll 1$, we have

$$V(\rho) \simeq (Z_1 Z_2 e^2 / \rho) \{ 1 - (k_D \rho) [\alpha \lambda(\alpha) + \theta(1 - \alpha^2)(1 - \alpha^2)^{1/2}] \} \quad (3)$$

Here

$$\lambda(\alpha) = (\pi/2) - \theta(1 - \alpha^2) \arctan[(1 - \alpha^2)^{1/2} / \alpha]$$

with $\theta(x)$ being the unit step function [$\theta(x) = 1$ for $x > 0$ and zero otherwise] and $\alpha = 3^{1/2}(\nu_s / \nu)$ where $\nu_s = (k_B T_e / M)^{1/2}$ is the ion sound velocity.

Since the factor $[\alpha \lambda(\alpha) + \theta(1 - \alpha^2)(1 - \alpha^2)^{1/2}]$ does not exceed $\pi/2$, the dynamic screening at a small distance may be ignored. But the second derivative of this factor with respect of ν is proportional to

$$\theta(1 - \alpha^2) / (1 - \alpha^2)^{1/2}$$

which becomes extremely large as $\alpha^2 \rightarrow 1-0$ [$\alpha = 1$ corresponds to the case where $\omega (= \nu k_z)$ is equal to the angular frequency of the ion-sound waves⁴, $\nu_s(3k_z^2)^{1/2}$]. To introduce a further simplification, I note that the reaction which starts the fusion is the one involving a head-on collision. So, I consider $V(\rho)$ given previously as the modified Coulomb interaction between the nuclei and the velocity ν in it as the relative velocity, ignoring the effects of the centre-of-mass (CM) motion, of two colliding nuclei in the plasma.

With this modified Coulomb repulsion, I obtain, using a standard method⁵, the thermonuclear reaction rate $r = n_1 n_2 \langle \sigma v \rangle$ (where n_1 and n_2 are the number densities of the colliding nuclei) as

$$\langle \sigma v \rangle \simeq \langle \sigma v \rangle_0 |g|^{-1/2} \exp \{ \epsilon_D [\alpha_0 \lambda(\alpha_0) + \theta(1 - \alpha_0^2)(1 - \alpha_0^2)^{1/2}] / k_B T \} \quad (4)$$

where the lowest order in the expansion parameter ϵ_D / E_0 (with $\epsilon_D = Z_1 Z_2 e^2 k_D$) is kept. Here,

$$\langle \sigma v \rangle_0 = 4(2/3\mu)^{1/2} S_0 (E_0^{1/2} / k_B T) \exp(-3E_0 / k_B T)$$

with

$$E_0^{3/2} = (\mu/2)^{1/2} (\pi Z_1 Z_2 e^2 k_B T / \hbar)$$

and

$$\mu^{-1} = M_1^{-1} + M_2^{-1}$$

is the usual reaction rate per pair of nuclei for pure Coulomb repulsion α_0 is $\nu_s(3\mu/2E_0)^{1/2}$ and S_0 is a constant. For a 50% DT mixture, we have $S_0 \simeq 1.3 \times 10^4$ barn keV (in the CM system). The exponential factor in the above equation is, in practice, close to 1 because $(\epsilon_D / k_B T) \ll 1$. So no dramatic enhancement is expected from this factor. The factor g represents a feasible enhancement and it is given by

$$g \simeq 1 - (\epsilon_D / 6E_0) \theta(1 - \alpha^2) [\alpha^2 / (1 - \alpha^2)^{1/2}] \quad (5)$$

where

$$\alpha = \nu_s(3\mu/2E)^{1/2}$$

with

$$E \simeq E_0 \{ 1 - (\epsilon_D / E_0) [(4/3)\alpha \lambda(\alpha) - \theta(1 - \alpha^2)(1 - \alpha^2)^{1/2}] \}$$

In general $g \simeq 1$ except when $\alpha^2 \rightarrow 1 - (\epsilon_D / 6E_0)^2$ or, equivalently, T_e exceeds T such that

$$T_e / T \simeq (2M/3\mu)(3E_0 / k_B T) [1 - (2/3)(\hbar \Omega_p / k_B T)] \quad (6)$$

When the conditions implied in equation (6) are met, $g \rightarrow 0$ which gives the desired anomalous increase in $\langle \sigma v \rangle$. (For a superdense plasma where $T_e \ll T_F$, T_e in equation (6) should be replaced by $2T_F/3$. Here T_F is the Fermi temperature of the degenerate electrons.) For a 50% DT mixture, equation (6) becomes

$$T_e / T \simeq (28/T^{1/3}) [1 - 3.7 \times 10^{-3} (n_e / T)^{1/2}] \quad (7)$$

(The units of n_e and T are 10^{26} cm^{-3} and keV respectively.) For example, for $T = 5 \text{ keV}$, $T_e \simeq 82 \text{ keV}$ is required to satisfy equation (7). Since the bremsstrahlung losses³ are proportional to $T_e^{1/2}$, an additional loss is incurred when $T_e \gg T$ compared with the case when $T_e = T$. And one requires $|g| < (T/T_e)$ (or $|g| < 6.1 \times 10^{-2}$ in the case of a 50% DT mixture) to offset the losses.

In the case when $T_e \ll T$ so that $\nu \gg u_T$ as well as $\nu \gg \nu_T$, we have⁴

$$\epsilon(\mathbf{k}, \omega) = 1 - [\omega_p / (\omega + i\delta)]^2, \quad (8)$$

where $\omega_p = (4\pi n_e e^2 / m)^{1/2}$. In this case, we obtain

$$\langle \sigma v \rangle \simeq \langle \sigma v \rangle_0 [1 + (\hbar \omega_p / 6k_B T)] \times \exp \{ (3E_0 / k_B T) (\hbar \omega_p / 6k_B T) \} \quad (9)$$

Thus, for a superdense plasma, a huge enhancement is expected from the exponential factor. But at such a high density T_F exceeds T , and T_e should be replaced by $2T_F/3$ in μ_T when $T_e \ll T_F$. So in order to have a significant enhancement, we should also require $T \gg T_F$ which gives a limit on n_e as

$$n_e \ll (3\pi^2)^{-1} (2mk_B T / \hbar^2)^{3/2}$$

[or $n_e \ll 1.4 \times 10^{26} T^{3/2} \text{ cm}^{-3}$ (T in keV) for a 50% DT mixture]. I note that even at $n_e = 10^{26} \text{ cm}^{-3}$, $\langle \sigma v \rangle / \langle \sigma v \rangle_0$ is only about 1.2 for a 50% DT mixture at $T = 5 \text{ keV}$. Thus, one finds no significant increase in $\langle \sigma v \rangle$ when $T_e \ll T$.

In conclusion, dynamic screening has a negligible effect in most circumstances, except when T_e exceeds T by the amount

given by equation (6). In this case, an anomalous enhancement in thermonuclear reaction rates occurs

Garden hose separation of gaseous isotopes

METHODS of separation of isotopes and in particular the separation of uranium isotopes, have long been studied^{1,2}. Here I present a new variation of the "time-of-flight" process, applicable to all gaseous isotopes, although UF_6 gas is considered as the example.

The time-of-flight separation is basically a mechanical analogue of a diffusion barrier. As a cloud of gas moves through an evacuated region, the faster moving lighter molecules concentrate toward the outer portion of the beam configuration, and when they are collected they are enriched in the light component. Similarly, the inner portion would be depleted in the light component when collected. But a continuous and stationary source beam would not give rise to separation as the inner portion of one layer of cloud is equivalent to the outer portion of the subsequent layer of cloud. A 'chopper' is therefore required to cut the beam into individual layers, and extensive pumping is needed to evacuate the system sufficiently to maintain the integrity of the cloud during their time of flight.

During World War II, Bagge designed such an apparatus³, with synchronised choppers, collectors, and powerful pumps, a cascade of such time-of-flight units were constructed to separate the uranium isotope. But the necessity of operating that system at very low gas pressure and with limited efficiency of collection are major drawbacks implying low throughput and high consumption of pumping energy.

Fig. 1 Schematic relationship between the population fronts and the collectors B, C_e, and C_d, where η is the angular span of collector B. B and C_e are for enriched light component, while C_d is for depleted light component. Δr is the mean separation of the population fronts.

Fig. 2 A diagrammatic plan view of the centrifugal separating chamber with three circular compartments at the wall storing the enriched, depleted, and to-be-recycled concentrations. For $v_e \approx 2v_0$, there are six ejection outlets symmetrically disposed in a plane of rotation, with each outlet standing for three separate outlets stacking on top of each other for their corresponding storage chambers.

In the technique I propose, the gas molecules are channelled into an evacuated chamber through a set of rotating supersonic nozzles at a small retarding angle so that the ejected gas has zero angular momentum. Once inside the vacuum chamber, molecules travel according to their corresponding thermal velocities plus a common ejection velocity v_e , and from

$$mv_0^2/2 = 4kT/\pi = \text{constant} \quad (1)$$

the difference in mass gives,

$$\Delta v_0 = -\Delta mv_0/2m = -(2kT/\pi m)^{1/2} \Delta m/m \quad (2)$$

From the Maxwellian equal partition relationship, we have $\Delta v/v = -\Delta m/2m$ in general. After time t , while the ejection velocity carries the molecules to a distance $R = v_e t$ from the nozzle, the thermal velocity would carry them into spherical fronts of radius r centred at the end point of R , and the separation of the fronts Δr is

$$\Delta r = \Delta vt = -\Delta mvR/2mv_e = 0.426\% \text{ of } vR/v_e \quad (3)$$

for UF_6 .

The molecular fronts are now in the form of a ball (thermal velocities) on top of a cone (ejecting velocity), so the objective is to design rotating collectors to skim the surface of the ball most effectively in order to collect a substantial portion of the concentrations separated by the two sides of the ball surfaces. Figure 1 is a schematic of collectors C_e (for the enriched front), C_d (for the depleted front) and B (for the relatively stationary collector of the original Becker design), the angular width of collector B can be shown as $\approx 2 \cos^{-1} (1 - \Delta r/r) \approx 10^\circ$.

Once the molecule enters the collector, it would be swung toward the chamber wall by the centrifugal force, and it is stored and pressurised by the rotating wall outside the chamber. For $v_e = 2v_0$, there can be as many as six sets of nozzle-collector combinations operating at the same plane (Fig. 2). The storage chamber has three compartments for enriched, depleted, and to-be-recycled concentrations. The last part is

mainly the 'unskimmed' portion which is channelled back to the original nozzles that ejected them. There are no moving parts relative to the chamber in this collector-nozzle-chamber combination, and by operating under vacuum (~ 0.1 torr), UF_6 can be stored in its solid form so that the flow can be controlled by thermal evaporation as well.

Following the Maxwellian distribution, the normalised population density $n(v)$ is,

$$n(v) = (m/2\pi kT)^{3/2} 4\pi v^2 \exp(-mv^2/2kT) \quad (4)$$

where

$$\int_0^\infty n(v) dv = 1$$

and

$$\int_0^\infty n(v) v dv = (8kT/\pi m)^{1/2}$$

Consider first the high energy Maxwellian tail, for $v' \geq v_0$, let $v^2 = v'^2 + u$, $2kT/m$ and $g \equiv mv'^2/2kT$, so the fractional population at the tail portion is

$$\begin{aligned} n(v \geq v') &= \int_{v'}^\infty n(v) dv = (2/\sqrt{\pi}) e^{-g} \int_0^\infty (u+g)^{1/2} e^{-u} du \\ &= (2/\sqrt{\pi}) e^{-g} [g^{1/2} + 1/2 g^{-1/2} - 1/4 g^{-3/2} + \dots] \end{aligned} \quad (5)$$

and calculate the increment Δn by differentiations of $n(v)$ and integrate,

$$\Delta n(v \geq v') = (-4/\sqrt{\pi}) e^{-g} g^{3/2} \Delta v'/v' \quad (6)$$

then

$$\Delta n/n \simeq [-8g^3/(4g^2+2g-1)] \Delta v'/v' \quad (7)$$

Similarly, at the low energy part of the spectrum where $g \ll 1$,

$$n(v \leq v') \simeq (4/\sqrt{\pi}) g^{3/2} (1/3 - g/5 + g^2/14) \quad (8)$$

and

$$\Delta n/n \simeq e^{-g} (\Delta v'/v') / (1/3 - g/5 + g^2/14) \quad (9)$$

Figure 3 shows plots of equations (5)–(9). Clearly, concentrating on the high energy tail alone, α can be made as large as that of total separation, only at the expense of reducing the total fractional population by the Boltzmann factor e^{-g} . The depleted fractional from equation (9) has a relatively stable separation at $\Delta n/n \simeq 1\%$.

I now make a simple estimate of the specific power requirement of the 'gross-cut-mode' from equations (7) and (9). Let y be the enriched stream, x the depleted stream, θ the cut of separation, then $y = \theta(1 + \Delta n/n)$, $x = (1 - \theta)(1 - \Delta n/n)$, and from $\alpha \equiv (y/(1-y))/(x/(1-x))$, ignoring terms with $(\Delta n/n)^2$, we have

$$\alpha \simeq \theta(1 + \Delta n/n) / [(1 - \theta)(1 - \Delta n/n)] \quad (10)$$

Choose $|\Delta n/n| \simeq 1\%$ for both x and y , so from Fig 3,

$$n(v \geq v' \text{ at } g \simeq 2) \simeq 25\% \simeq n(v \leq v' \text{ at } g \simeq 0.7)$$

and let the collectors catch one-half of the designated fractionals, so one-quarter of the population is processed while

Fig. 3 Concentrating on the high energy tail of the Maxwellian distribution, $\alpha \simeq 1 + 4\Delta n/n$ can be made large at the expense of reducing fractional population collected. At the low energy end, $\Delta n/n$ is relatively stable at 1%. A crude estimate of processing a quarter of the population at each end of the spectrum gives a specific power consumption only one-fifth that of the minimum theoretical diffusion requirement.

three-quarters is channelled back to the nozzles to be recycled. With $\theta = 1/2$, from equation (10),

$$\alpha \simeq 1 + 4\Delta n/n \simeq 1.04 \quad (11)$$

Let $R = 100$ cm, $r = 50$ cm, and the height of the chamber $D \simeq R + r = 150$ cm, $\Omega = 2\pi \times 30$ Hz so the velocity of the collector $v_c \simeq \Omega R \simeq 2v_0$ at room temperature. The mean free path $\lambda \simeq D \simeq 150$ cm so the pressure $P_0 = n_0 kT \simeq 1.75 \times 10^{-2}$ dyne cm^{-2} with molecular diameter $\simeq 6$ Å. Because of the centrifugal pumping, once the molecules are caught by the collectors, the gas pressure is raised by the factor $mv_c^2/2kT = 5.8$ so pressure in the collector $P_c \simeq 0.1$ dyne cm^{-2} . The number of molecules N flowing through the processing chamber per second is

$$\begin{aligned} N &= 6 \times v_c \times n_0 \times \pi(D/2)^2 \\ &= 1.2 \times 10^{21} \\ &= 0.7 \text{ g of } \text{UF}_6 \\ &= 15 \text{ t of uranium per year} \end{aligned} \quad (12)$$

The separating collectors carry only a quarter of this value, so the throughput is $15 \times 1/4 = 3.75$ t yr^{-1} . The power requirement for the collectors and the shields acting as a centrifugal pump is

$$0.5 mv_c^2 \text{ s}^{-1} = 28 \text{ W} \quad (13)$$

By balancing the compression energy of the gas with that of the jet flow of $0.5 mv_c^2$ at 25 W, the nozzle opening should be about 0.5 cm and from the continuity of flow, $P_{\text{nozzle}} = P_0 \times (150/0.5)^2 = 9 \times 10^4 P_0$, so the additional compressional power required is

$$(m/M) RT \log(P_{\text{nozzle}}/5.8 P_0) \simeq 20.7 \text{ W}, \quad (14)$$

where R is the gas constant, M the molecular weight of UF_6 and

\dot{m} the mass flow in g s^{-1} . The Unit-of-Separative-Work (USW) done for each stage is now,

$$\begin{aligned}\text{USW} &= \text{Throughput} \times (\alpha - 1)^2 / 2 \\ &= 3.75 \times 10^3 \text{ kg yr}^{-1} \times 0.04^2 / 2 \\ &= 3.0 \text{ kg yr}^{-1}\end{aligned}\quad (15)$$

and the specific power requirement is,

$$\frac{1}{2} (0.028 + 0.0207) = 0.0162 \text{ kW}/(\text{kg USW}) \text{ yr}^{-1}, \quad (16)$$

which is only 22% of the theoretical minimum requirement of the diffusion process ($0.073 \text{ kW}/(\text{kg USW}) \text{ yr}^{-1}$). The throughput of this method is relatively low so the specific capital cost may be higher. On the other hand, by using UF_6 in a solid form for storage, together with a much higher separation coefficient, the number of processing stages required can now be reduced by over an order of magnitude. The present method also compares favourably with a centrifuge in terms of centrifugal force requirement and the choice of variable separation constant α .

Some of the recent methods of multistage preferential heating of isotopes by lasers can also be incorporated into the present method, as the time-of-flight vacuum chamber preserves the original state of motion as well as that added and the chamber dimension near the axis of rotation is such that it can easily accommodate these additional arrangements.

I thank Dr M. Benedict of MIT for showing me related literature, my colleagues in Combustion Engineering for comments and Mr A. Davis for drawing Fig. 2.

Radium removal from drinking water

RADIUM is absorbed from natural waters on to acrylic fibres impregnated with oxides of manganese¹. This extraction technique, developed for oceanographic studies, is also effective in removing radium from drinking water.

Radium-226, a naturally occurring radioactive daughter of ^{238}U , presents a potential health hazard when dissolved in ground waters. The body metabolises radium and calcium similarly, if radium is available to the bloodstream, it will concentrate in the bones². Radioactive decay of ^{226}Ra within the bones exposes the skeleton to highly ionising, short range alpha particles as well as more penetrating beta and gamma radiation from radium daughters. The most immediate effect of this radiation is to increase the chances of developing osteosarcoma and other cancers². Although the exact relationship between the low level radium exposure and cancer risk is not known, there is probably no safe level of human exposure to radium. The drinking water standards published by the United States Public Health Service recommend³ a level not exceeding 3 pCi l^{-1} ($6.66 \text{ d p m l}^{-1}$).

Fig. 1 Concentrations of ^{226}Ra measured in the water from the well and in the effluents from two columns filled with manganese-fibre. The first 500 l were processed at 4.3 to 6.2 l min^{-1} , the remainder at 7.5 to 8.2 l min^{-1} . The variable slopes of the first column effluent reflect this difference in flow rate. a, Well effluent, b, first column effluent, c, second column effluent. ---, US Public Health Service drinking water limit.

Commercial grade uranium deposits in south Texas have been mined since the late 1950s. In 1971, elevated ^{226}Ra levels were measured in well water near the edge of the Felder uranium ore body near Three Rivers, Texas⁴. Other wells in the south Texas area have been surveyed and a small fraction produce drinking water with radium levels above the United States Public Health Service Standard⁵. One of these wells, referred to as Whitley well No. 1, is located about 8 km south-west of George West, Texas. This well has a ^{226}Ra concentration of 110 pCi l^{-1} , the second highest level measured in recent surveys of this area⁵. Small deposits of uranium occur within 300 m of this well, a high grade uranium deposit is being mined within 8 km. These localised ore bodies are believed to be the sources of radium found in the well waters of south Texas. Wells known to produce water high in ^{226}Ra have been removed from use as routine drinking water sources.

Acrylic fibre impregnated with manganese has been used to remove radium from seawater. We prepared similar fibre using the procedure described by Moore and Reid¹. The resulting fibre contained 12–15% Mn by weight when dry.

Two water filtering columns connected in series were each filled with 40 g of Mn fibre. The columns were attached to Whitley well No. 1. A water meter attached downstream of the columns recorded the volume of water processed. Water samples were periodically drawn (a) directly from the well, (b) from the column 1 effluent, and (c) from the column 2 effluent. These samples were stored for ^{226}Ra determinations using the ^{222}Ra emanation technique⁶.

Initially the flow rate decreased slightly due to packing of the Mn fibre. By adjusting the water pressure we attained a steady flow of 7.5 to 8.2 l min^{-1} after about 550 l had passed through the system. The experiment was terminated after 2,650 l had been processed.

Our objective was to determine if radium could be effectively and inexpensively removed from this well water. Figure 1 shows that radium removal from this highly contaminated well by two Mn-fibre columns was essentially complete for 1,300 l. After 1,300 l had passed through the system, the column 2 effluent was 3 pCi l^{-1} , the Public

Health Service recommended drinking water limit. After 2,650 l of water had been processed, the outflow from column 2 still had less than 10% of the ^{226}Ra concentration of water entering the system. We conclude that radium removal from highly contaminated ground waters is technically feasible using manganese impregnated fibres. Although this experiment represents only one well, our success with this water as well as similar success with seawater and brackish water which contain high concentrations of calcium and magnesium¹, makes us optimistic about the general applicability of the Mn-fibre technique for removing radium from drinking waters.

The cost of removing radium using the Mn fibres is low. The fibre can be prepared for about \$15.00 per kg. One kilogramme fibre would bring the radium level of more than 10,000 l of the water from Whitley well No 1 to within the United States Public Health Service limit. This would be adequate drinking water for a family of four for 3 yr (ref. 7). Since most wells in the area have ^{226}Ra levels much below that of Whitley well No 1, the 10,000 l figure is a minimum. We conclude that manganese fibres can provide an inexpensive means of removing radium from drinking water.

We emphasise that this work is still in the testing stage. Any attempts to decontaminate drinking waters with respect to radium should be conducted only under the supervision of local health authorities.

We thank Mr and Mrs Sonny Whitley for the use of their well. Encouragement from Dr H. C. Eppert, jun and Dr Morris Schulkin of NAVOCEANO and Mr Martin Wukasch, P.E., Director, Division of Occupational Health and Radiation Control of the Texas State Health Department is acknowledged.

Methylation of lead in the environment

LEAD is one of the most toxic metals found in the environment and is of great concern because of its widespread occurrence in nature, but its fate is largely unknown¹. Much of the lead dispersed by man is eventually washed into natural waters and is presumably precipitated into the sediments². The methylation of mercury and arsenic by microorganisms in the environment has been documented and well summarised³. Nothing, however, has been known about the existence of organic forms of lead in the environment as a result of biotransformation⁴.

Here we present evidence for the first time, that microorganisms in lake sediments can transform certain inorganic and organic lead compounds into a volatile tetramethyl lead (Me_4Pb). Experiments were carried out with 50 g of sediment and 150 ml of lake water from Hamilton harbour (Lake Ontario), Mitchell Bay (Lake St. Clair), and Erieau harbour (Lake Erie), placed individually in a

250 ml filtering flask fitted with a side-arm. Nutrient broth (0.5%) and glucose (0.1%) were added to stimulate the microbial growth and the flask was capped and sealed. Nitrogen was bubbled in to create an anaerobic condition but this practice was later discontinued because the microbial growth was sufficient to generate the anaerobic condition. After incubation for 2 weeks at 20°C, the gas phase in the incubation flasks was withdrawn through the side-arm by means of a peristaltic pump and transferred to a U-tube containing 3% OV-1 at -70°C. The sample trapped in the U-tube was swept into a gas chromatograph-atomic absorption spectrophotometer system for the separation and analysis of the volatile lead compound. Tetramethyl lead was detected in the air sample with reference to the retention time of a synthetic compound. The identity of the Me_4Pb peak in the air sample was further confirmed by gas chromatography and mass spectrometry. Addition of inorganic lead nitrate or organic trimethyl lead acetate (Me_3PbOAc) at 5 mg (expressed as lead) per litre of sample greatly increased the Me_4Pb production. Not all sediment samples we examined, however, produced Me_4Pb in identical conditions to those described above. In some cases, the addition of inorganic lead nitrate or chloride failed to affect the transformation but in all cases the transformation of Me_3PbOAc to Me_4Pb was observed. There was no transformation if the systems were autoclaved. Ultraviolet light irradiation caused no conversion of Me_3PbOAc to Me_4Pb in the absence of microorganisms, so ruling out the possibility of chemical disproportionation reactions⁵, activated by ultraviolet light.

Direct chemical synthesis of methyl lead compounds through alkylation of inorganic lead salts is very difficult because of the extreme instability of the postulated first intermediate monomethyl lead salts. We have observed the conversion of lead nitrate and lead chloride to Me_4Pb on several occasions in lake sediments but no Me_4Pb transformations have yet been detected from lead hydroxide, lead cyanide, lead oxide, lead bromide, or lead palmitate. In none of these experiments were Me_3Pb^+ salts detected in the culture medium, although it is a stable intermediate in the chemical pathway of the successive methylation. (The analysis for trimethyl lead salts was specially developed in our laboratories in support of this study.)

The pathways for the biological conversion of lead are not well understood. It is apparent that the conversion of inorganic lead to organic lead is a difficult process and it probably requires specific physical, chemical, as well as biological conditions. On the other hand, the biological methylation from Me_3Pb^+ to Me_4Pb seems to proceed quite readily and we were able to demonstrate this conversion with pure species of bacterial isolates from Lake Ontario without the presence of sediment. We found that species of *Pseudomonas*, *Alcaligenes*, *Acinetobacter*, *Flavobacterium*, and *Aeromonas* growing in the presence of nutrient broth (0.5%), glucose (0.1%) and yeast extract (0.1%) could transform Me_3PbOAc into Me_4Pb . None of the isolates was able to produce Me_4Pb from inorganic lead in chemically defined media.

Weekly sampling of the atmosphere in the incubation flasks was carried out to determine the rate of conversion of Me_3PbOAc to Me_4Pb . With 10 mg of lead (as Me_3PbOAc) in the sample, 125 µg of lead (as Me_4Pb) was detected after incubation for 1 week. The conversion rate increased to 642 µg in the second week and declined to 550 µg and 256 µg of lead in the third and fourth weeks respectively. The decrease in lead conversion after 2 weeks could be due to the exhaustion of nutrients, accumulation of toxic metabolic products, or changes in pH in the medium. Assuming that 642 µg of lead is the maximum rate for the conversion, the microorganisms were able to convert 6% of lead in one week.

The toxicity of Me_4Pb towards algae was studied by

bubbling the biologically generated Me_4Pb from one flask (containing 5 mg Pb l^{-1} as Me_3PbOAc) into the culture medium in another flask where a test alga *Scenedesmus quadricauda* was grown. As Me_4Pb is not soluble in water and is volatile, the exposure of an alga to this lead compound was only momentary. We estimated that less than $0.5 \text{ mg Pb}(\text{Me}_4\text{Pb})$ had passed through the culture medium. We found that the primary productivity and cell growth (determined by dry weight), however, decreased by 85% and 32% respectively, as compared with the controls without exposure to Me_4Pb . Furthermore, cells exposed to Me_4Pb tended to clump together. Similar results were obtained with *Ankistrodesmus falcatus*. To obtain similar inhibition, twice as much lead, in the form of Me_3PbOAc , and twenty times as much lead nitrate would be required. These numbers were calculated from our studies on the toxicity of various forms of lead compounds on algae.

We conclude from the results of 50 experiments that incubation of some lead containing sediments generates Me_4Pb , that Me_3Pb^+ salts are readily converted to Me_4Pb by microorganisms in lake water or nutrient medium, with or without the sediment, and in the presence or the absence of light, that conversion of inorganic lead (such as lead nitrate or lead chloride) to Me_4Pb occurred on several occasions in the presence of certain sediments, and that the conversion is purely a biological process.

A study of age group track and field records to relate age and running speed

AGE affects man's ability to run fast but to date there has been little interest in quantitating the relationship. The few published studies, such as the one by Dill on marathon runner Clarence DeMar¹, are concerned mainly with reporting lung volume, heart rate, and other physiological characteristics of notable performers, with only brief reviews of race performances over the runner's life span.

Two recent compilations of track and field records present an opportunity to study ageing effects on running speed. One contains records for men², in 1-yr age groups for ages 1 to 78, and the other contains women's records³, in 1-yr age groups for ages 3 to 60. This study was designed to determine how rapidly running speed deteriorates with age and whether the rate of deterioration depends on the length of the race, and to compare deterioration rates of running speed, strength and stamina in men and women.

When speed (m s^{-1}) is plotted against age, it is evident that speed improves up to age 20 or so and gradually deteriorates beyond age 30. Between ages 20 and 30, running speed is near the maximum and almost constant for all distances included in the records (100 m, 200 m, 400 m, 800 m, 1,500 m, 3,000 m, 5,000 m, 10,000 m and marathon (42,195 m)). An exponential model was chosen to fit the age records for each distance.

$$Y = A_1 [1 - \exp(A_2 X)] + A_3 [1 - \exp(A_4 X)],$$

where Y is the speed in m s^{-1} , X is the age in years, and the constants A_1 , A_2 , A_3 , A_4 are determined from the age records by the method of least-squares. This model has the advantage of fitting the data well over the entire age range, whereas the more usual Gompertz-type equations can be applied only to ages where speed is decreasing with age. In addition, this model allows the rate of increase in speed (under age 20) to differ from the rate of decrease (over age 30). The model also goes through the origin so that at zero age the speed is zero. Examples of the fit for several running events are shown in Fig. 1.

A comparison of the fit curves for all the men's running events reveals that age of maximum performance increases with distance. This is also true of the recorded data, where the sprint records are held by men in their early twenties but the marathon record-holder is 26 yr old. Comparison of the slopes of the fit curves reveals that speed deteriorates more slowly at longer distances than at shorter ones. For example, at age 50 speed in the 200 m sprint is slowing at a rate of $0.09 \text{ m s}^{-1} \text{ yr}^{-1}$ but for the marathon the rate is only $0.06 \text{ m s}^{-1} \text{ yr}^{-1}$. This observation suggests that strength deteriorates faster than stamina.

This hypothesis was tested further by fitting the exponential model to the age records for the men's shot-put and discus, events which are even more strength-dependent than the 200 m sprint. Direct comparison of the slopes for running events with those for the field events is not valid because the recording units differ. A comparison can, however, be made if all age records are converted to percentages of the world record.

Fig. 1 Running speed records by age. Exponential curves (for model, see text) were fitted to published age records: (a) Men's records for 200 m, 800 m, and marathon (42,195 m); (b) The 400 m records for men and women.

Table 1 Age records as percentages of world records

Age	Shot-put	Discus	200 m	Marathon
10	61	60	79	68
20	91	90	98	94
30	100	100	99	100
40	98	95	93	96
50	76	78	84	88
60	49	53	74	76

Percentages based on fitting the exponential model (see text), to published data

Thus, a speed of 8.12 m s^{-1} for the 200 m race is 80% of the world record speed (10.15 m s^{-1}), whereas a shot-put of 17.46 m is 80% of the corresponding world record (21.82 m). These comparisons (Table 1) lend further support to the hypothesis that strength deteriorates faster with age than does stamina.

Fewer data are available on women's age records (current records only include running events up to 3,000 m, and rarely are there records for women over 45 yr of age). A comparison with those for men suggests that girls mature faster than boys (with respect to running events) in the age range 8–12 yr. For example, at ages 8, 9 and 11 women's records are faster than those for males in the 400 m run (see Fig. 1b). It also appears that beyond age 30, speed deteriorates at a faster rate for women than for men. For example, the fit curves show that in the 100 m sprint the women's record at age 45 is 85% of the women's world record, whereas the corresponding figure for men is 90% of the men's world record.

The records analysed here comprise the marks of many individual athletes but they can be thought of as those set by a 'super' runner, one who is in top condition throughout his life span. The ordinary runner is one whose speed is slower, perhaps by some fixed amount over the entire age span, than that of the super runner. The speed curve for the ordinary runner may have the same shape as that of the super runner and the rates of change of speed with age would be the same. This hypothesis could be tested by following up several runners over their life spans, recording annually their running times over measured distances. This could be done retrospectively, by contacting those who have run for a number of years and determining their best times at various distances each year.

This work was carried out under the auspices of the United States Atomic Energy Commission.

The capacity for joint visual attention in the infant

LITTLE is known about how visual attention of the mother-infant pair is directed jointly to objects and events in the visual surround during the first year of the child's life. To what extent does the child follow the mother's lead and the mother the child's, and what are the processes involved? The ability of the infant to respond successfully to such signals allows the mother to isolate and highlight a much wider range of environmental features than if the infant ignores her attention-directing efforts. We report a preliminary investigation of the extent of the infant's ability to follow changes in adult gaze direction during the first year of life.

Mothers who had volunteered as subjects in response to

newspaper advertisements were asked to bring their infants into our laboratory at a time when the infant was 'usually active'. Thirty-four infants, 2–14 months old, were tested in a small, sparsely-furnished room (15 ft by 10 ft) with a one-way screen at one end and a window with drawn blinds at the other. The infant was placed in a highchair, appropriate to his age, in an upright position. The mother played with him until he seemed settled and was then replaced by the experimenter—either male or female in their twenties, unknown to the baby. It was not practicable to have the mothers as experimenters with the rather strict testing requirements used here although many observations were made prior to this on other mothers and infants in a similar, though less controlled, situation. The experimenter first played with the infant for a short period and, if the latter showed no signs of distress, the mother left the room. The experimenter remained seated in front of the infant, eyes at the same level, about 0.5 m away. The infant was then given two trials in a prearranged order.

On each trial the experimenter first made eye-to-eye contact then silently turned his (her) head through 90° to fixate a small (concealed) signal light, 1.5 m away, for 7 s. He then turned back to interact with the infant. Two trials were given, one involving a head turn to the right, one a turn to the left, with inter-trial intervals varying from 20 to 50 s, depending on difficulties in establishing subsequent eye-to-eye contact. The infant's behaviour was recorded by two concealed video cameras set at 45° to the experimenter-infant face-to-face axis, giving a split-screen 45° profile of the infant from two sides. The experimenter was not visible on the screen. The infants were also filmed for calibration looking at experimenter in fixed positions of known angular displacement.

Trials were scored from the videorecord by the experimenter, based on infant head movement only. A positive response was scored if the infant looked (a) in the same direction (right/left) but not down at the floor or up at the ceiling, (b) without an intervening look elsewhere (ignoring short looks down during postural adjustment), (c) within 7 s, and (d) appeared to be looking for or at something (involving halting the head turn for 0.5 s or more with a cessation of limb movement). The infant did not have to appear to be fixating exactly the same point. Scoring reliability was ascertained from three naive observers uninformed as to experimenter's judgment. They produced 96% agreement on trials scored as positive, 90% on those scored as negative.

The proportion of infants judged as having produced a positive response on one or both trials increases steadily with age (Table 1). The form of the response, that is, how soon and where the infants look, did not show systematic change with age. Latencies in response were very variable—any point up to the end of the trial, and the infants would look anywhere from about 20° to 90° away from the midline. Labelling responses as positive does not, of course, mean that infants were looking for something to look at. In the upper age groups, however, there was strong evidence to suggest this may be so with infants often looking away, looking back at the experimenter and then looking away again. This had been even more marked when the mother was the experimenter in earlier observations. Of the negative trials over 80% were comprised of responses where the infant either kept his eyes on the experimenter or looked down at the highchair table top.

The proportion successfully responding may well be depressed by the strangeness of the setting although the incidence

Table 1 Percentage of children judged as following line of regard in one or both trials

Age (months)	No. infants	% Showing positive response
2–4	10	30
5–7	13	38.5
8–10	6	66.5
11–14	5	100

of following line of regard is enhanced by pointing and exclamatory vocalisations such as "Oh look" By 11 months, however, some children gave unequivocal positive responses to eye movement alone Some (from 6 months) even followed line of regard when the experimenter and mother, not interacting with the infant, conversed a metre away from the child

It is possible that the ability to orient with respect to another has implications for Piaget's¹ more complex notions of the egocentric child In so far as mutual orientation implies a degree of knowledge in some form about another person's perspective then the child in its first year may be considered as less than completely egocentric The source of such abilities (for example, imitation) remains to be investigated but utilisation of another's gaze direction may be a very basic process Cooke's Hartebeeste (*Alcelaphus buselaphus*) on hearing a danger signal raise their heads, look at the signaller and orient in the direction he is facing (M Stanley-Price, personal communication) Such observations need careful investigation but it may not be entirely unexpected that human infants should also have greater abilities than has been supposed (for example, Schaffer²).

Role of juvenile hormone esterases and carrier proteins in insect development

THE discovery of a binding protein, specific for juvenile hormone (JH)¹ in the haemolymph of the tobacco hornworm, *Manduca sexta*, suggested that this protein carries JH molecules from the secretory organs (corpora allata) to the target sites We report here that the binding protein provides the hormone total protection from degradative enzymes present in the haemolymph throughout early larval life^{2,3} Just before the start of pupal differentiation, however, a new esterase appears in the haemolymph which is able to hydrolyse the protein-bound hormone We have also found that the binding protein at concentrations of 10^{-8} M strongly enhances the development-inhibiting action of JH on wing disk tissue *in vitro* These properties, taken together, demonstrate a carrier role for the binding protein, and give new insights into the control of hormone levels in the haemolymph

Two closely related forms of the binding protein (CP-1 and CP-2) were purified to homogeneity by gel filtration on Sephadex G-100 (0.005 M Tris-HCl, pH 7.3, 0.1 M NaCl), followed by ion-exchange chromatography on Biogel DEAE (0.005 M Tris-HCl, pH 8.3, 0.1–0.14 M NaCl gradient) and preparative isoelectric focusing (pH 4–6, 1% Ampholine, 500 V, 72 h) The binding proteins elute as a single peak from the Sephadex column but are separated on the ion-exchange column and are finally purified by isoelectric focusing Under these experimental conditions CP-1 ($pI = 4.8$) was the major binding protein (>75% of the total hormone binding capacity) and was used for subsequent studies The hormone-protein complex formed with pure CP-1 and that formed in crude haemolymph showed that same dissociation constant ($K_D \approx 10^{-7}$ M)¹ and slow dissociation rate ($t_{1/2} = 15$ min)

The JH hydrolytic activity in the haemolymph of fifth instar larvae can be separated into two distinct peaks by gel filtration on Sephadex G-100 (0.005 M Tris-HCl, pH 7.3, 0.1 M NaCl) The activity in peak I (molecular weight $\approx 10^6$) is totally inhibited by 10^{-4} M diisopropylphosphorofluoridate

Table 1 Carrier protein protection of JH against hydrolysis by esterase fractions isolated from haemolymph of fifth instar *M sexta* larvae

Esterase fraction	Hydrolysis of JH (%)	Protection (%)
	–CP* +CP†	
Peak I	43 0	100
JH-esterase A	74 70	5

Pure synthetic *Hyalophora cecropia* JH¹ (methyl *trans,trans,cis* 3, 11-dimethyl-7-ethyl-10,11-epoxytrideca-2,6-dienoate) labelled in the chain (7-ethyl-1,2-³H, 67 mCi mg⁻¹ (New England Nuclear Corp) was used Reaction products were separated and identified by thin-layer chromatography according to the method of Slade and Zibitt² and quantitated by liquid scintillation counting

*Incubation for 15 min at room temperature of 20 μ l esterase and 10 μ l JH (8×10^{-7} M) followed by addition of 10 μ l carrier protein (4×10^{-5} M), incubation for 2 min and then addition of 10 μ l charcoal (4.5 μ g) to remove unbound JH Charcoal removed by centrifugation at 8,000g for 2 min Supernatant applied immediately to thin-layer chromatographic plate for analyses

†Same procedure as described for –CP but CP and JH were pre-incubated for 2 min before addition of esterase

(DFP) (pH 7.0, 15 min) whereas that in peak II (molecular weight $\approx 6 \times 10^4$) is unaffected under the same conditions Using this concentration of DFP, the crude haemolymph can be assayed for the two types of esterases Enzyme class II has been further purified by preparative isoelectric focusing (pH 4–6, 1% Ampholine, 500 V, 72 h) and three closely related forms (JH-esterases A, B and C) were separated All three forms show equal rates of hydrolysis of JH, and JH-esterase A was routinely used for our experiments

The hydrolysis of the hormone by JH-esterase A was measured in the presence and absence of binding protein CP-1 Table 1 shows that none of the enzymes of family I can hydrolyse JH complexed to CP-1 On the other hand, JH-esterase A hydrolyses the hormone even in the presence of a large excess of CP-1 In an attempt to correlate the presence of JH-esterases with the levels of JH in the insect, we examined the haemolymph from fourth instar larvae and found that esterases of type II are virtually absent In view of these results it was of interest to study the level of type II esterases during the critical premetamorphic period of the fifth instar Figure 1 shows that the level of the JH-esterases increases considerably and reaches a peak on day 5 of the fifth instar while type I esterases show relatively little variation during the same period

These results suggest important functions of both the binding protein and JH-esterases in the regulation of the JH level in the haemolymph during larval development In the early instars, where high levels of JH are required, the binding protein is necessary to protect JH from degradation by type I esterases Because of the continuous presence of these esterases, only JH complexed to the binding protein can reach the target tissues and thus the binding protein is the true carrier in the haemolymph In the fifth instar, on the other hand, type II esterases could constitute the most important factor in lowering the JH level in the haemolymph, thus permitting metamorphosis

To test further the participation of the carrier protein in the inhibitory action of JH in insect development, we used the technique of Oberlander and Tomblin⁴ This method measures the action of JH in terms of the inhibition of ecdysone-induced cuticle deposition in tissue cultures of imaginal wing disks from the Indian meal moth, *Plodia interpunctella* Table 2 shows the considerable synergistic action exerted by low levels ($< 10^{-8}$ M) of *M sexta* carrier protein on JH inhibition of *Plodia* wing disk metamorphosis The protein alone has no effect in this system Thus the carrier protein acts not only in haemolymph during transport of the hormone but also at the target issue Because of the high level of hormone and the very low level of carrier protein (well below K_D) required to evoke a large synergistic effect, it is unlikely that this is simply a protective effect of the carrier against degradative enzyme, which is known to occur in disk tissue⁵ Rather, the

Fig. 1 Activity of general and JH-esterases in the haemolymph of fifth instar *M sexta* larvae of different ages. Haemolymph was collected as previously described¹ and kept at -20°C until used. Activities were assayed using a newly developed charcoal assay method and specially prepared *M sexta* JH (methyl *trans, trans, cis* 3,7,11-trimethyl-10,11-epoxydodeca-2,6-dienoate) labelled in the ester methyl group (methyl- ^3H , 8.3 mCi/mmol⁻¹), (L L S, K J K, F J K, and J H L, unpublished). The reaction mixture was composed of 50 μl of JH solution ($4.45 \times 10^{-5}\text{ M}$) in 0.1 M phosphate buffer, pH 7.0, 10 μl of 10% methanol and 50 μl of haemolymph in a 5 ml centrifuge tube. The reaction was quenched with 10 μl glacial acetic acid after which 100 μl charcoal suspension (0.045 mg) was added. The sample was mixed thoroughly and allowed to stand for 20 min and then centrifuged at 15,000g to sediment the charcoal. An aliquot of the supernatant was removed and the amount of radioactive methanol liberated was determined by liquid scintillation counting. DFP-inhibited samples (●) represent JH-esterase activity while non-DFP-inhibited samples represent total JH hydrolytic activity in the haemolymph. General esterase activity toward JH (○) is the difference between JH-esterase and total JH hydrolytic activities. Gut purging preparative to metamorphosis occurs on day 7 in our *M sexta* colony.

carrier probably serves a function in hormone recognition or transport at the target tissue. High molecular weight lipoproteins have been suggested as JH carriers in saturniid moth pupae and adults⁶ and in adult locusts⁷. In the *Plodia* tissue culture system, preliminary results indicate that the lipoproteins from *Hyalophora cecropia* and *P interpunctella* had no observable synergistic effect.

By their ability to degrade carrier-bound hormone and by the schedule of their appearance in the haemolymph, the JH-esterases of type II can lower the JH level at the critical time for the induction of metamorphosis. Because non-hydrolysable JH analogues are considerably more active than JH itself in bioassays⁸, it is possible that the JH-esterases are the determining factor in the control of metamorphosis.

Table 2 Effect of *M sexta* carrier protein on cuticle deposition in cultured imaginal wing disks of *Plodia interpunctella*

[JH]* $\times 10^4\text{ M}$	Inhibition of cuticle deposition (%)		
	CP absent	$4 \times 10^{-9}\text{ M CP}$	$8 \times 10^{-9}\text{ M CP}$
0	0	0	0
1.7	15†	—	—
2.1	28†	50†	100†
4.2	30	70	—

In each experiment the mesothoracic wing disks were removed from 10 *Plodia* larvae weighing 12–15 mg. Each pair of disks was divided between experimental and control culture dishes. Fat body was removed from the same larvae and was present in all culture dishes. Either 200 or 400 μl of modified Grace's medium was used in glass micro-dishes containing 10^{-6} M β -ecdysone. Unless otherwise noted, 10 wing disks were used for each experiment. Imaginal disks in this culture system produced tanned cuticle which was scored using a dissecting microscope.

*The juvenile hormone was a mixture of geometric isomers of *Cecropia* juvenile hormone provided by Hoffman-LaRoche.

†Twenty disks were examined.

‡Forty disks were examined.

It is tempting to extend our conclusions to insects other than *M sexta* since a similar low molecular weight carrier protein has been detected in larvae of *P interpunctella*⁹. In addition, we have tentatively identified a low molecular weight carrier in *H cecropia* larvae. The timetable for metamorphosis in all holometabolous insects is very similar and thus a degradative enzyme specific for the hormone-carrier complex could indeed be universally involved in the control of metamorphosis.

We thank Drs L. I. Gilbert and S. M. Ferkovich for supplying lipoproteins from *H cecropia* and *P interpunctella*.

A neuroendocrine feedback mechanism in the insect moulting cycle

THE principles of neuroendocrine integration and regulation developed by the Scharrers^{1,2} are central to current concepts of the regulation of the hypothalamo-hypophyseal system and are applicable to all neurosecretory systems. The importance of these principles in the regulation of the analogous system in insects (the protocephalic corpus cardiacum-allatum system) has, however, been little studied. Here I illustrate certain general functional parallels in the regulation of the vertebrate and insect systems by reference to work on the regulation of the neurosecretory pathway controlling moulting in *Rhodnius prolixus*.

Classical studies^{3,4} have shown that moulting in fifth instar *Rhodnius* is initiated at feeding by the release of a neurosecretory 'brain hormone' which is necessary for 6–8 d after feeding if the moulting process is to proceed to ecdysis. After this 'critical period' the continued release of 'brain hormone' is unnecessary and the secretory behaviour of the medial neurosecretory cells (MNC), which produce it, changes at about this time⁵. The principles of neuroendocrine integration suggest that this change would be implemented after appropriate information had been received by the brain indicating the effectiveness of its released neurosecretory material (NSM). As the principal known effect of this NSM is stimulation of the production of the moulting hormone, ecdysone, experiments have been devised to determine whether the changes in the cyfological behaviour on the MNC about the time of the 'critical period' are mediated by the increased haemolymph titre of ecdysone. If this is the case, it should be possible to induce

them prematurely by providing the insect with a supply of ecdysone before its endogenous course of the hormone has become fully active

In fifth instar *Rhodnius* decapitated 8 d after feeding all known endocrine centres are removed except those producing ecdysone, and the release of ecdysone continues⁶ *Rhodnius* decapitated at 8 days therefore provided insects with intact cerebral neuroendocrine systems early in their moulting process (1 d after feeding) to a sustained prematurely high physiological titre of ecdysone, using parabiosis. When serial sections of the brain (stained with paraldehyde fuchsin) from insects after 7 d of parabiosis (that is, on the eighth day after feeding) were examined, the MNC had been induced to switch over from their normal sequence of cytological changes to those characteristic of the older insect⁷. In particular, a massive number of Type 2a cells is produced during a period when they are otherwise absent, and there is a corresponding decrease in the number of cell Types 2 and 1 (Table 1). Such changes are induced by the haemolymph of donor insects which have passed the 'critical period' but not by that of insects which have yet to reach it. Thus the changes observed in the MNC during the normal moulting cycle⁸ are not an immutable sequence of events but respond dramatically to changes in the composition of the circulating haemolymph.

More direct evidence that ecdysone is the factor responsible for these effects on the MNC has been sought using synthetic hormones. The brain was exposed to a prematurely elevated titre of synthetic ecdysone by injection of 1 µg β-ecdysone in 1 µl sterile Ringer solution at 1 d and 3 d after feeding. The two separate injections were given in an attempt to maintain high ecdysone titres from 1–8 d after feeding and minimise any inactivation of the hormone by the fat body⁸. The MNC were examined on the eighth day as before. Ringer-injected controls were normal but the MNC of insects receiving β-ecdysone were strikingly similar to those of insects exposed to the hormone using parabiosis (Table 1).

Ecdysone administration clearly influences the cytology of the MNC. The observed effects of ecdysone are not normally encountered before the 'critical period' but are characteristic of normal insects which have passed it⁸ and which contain the hormone^{9,10}. Therefore, the changes in the cytological behaviour of the MNC which occur at the 'critical period' in normal insects are probably brought about by ecdysone. This indicates a feedback relationship between the prothoracotrophic 'brain hormone' and ecdysone: the behaviour of the MNC producing the 'brain hormone' changes with the increased titre of ecdysone, the production of which it stimulates. These changes are normally accomplished at the 'critical period', after which the moulting process is independent of the brain but if a premature independence from the 'brain hormone' is experimentally impressed on the insect by an exogenous supply of ecdysone, the MNC behave as though the period during which such independence is normally achieved, had arrived.

Reasoning has been presented elsewhere that the cytological changes induced by ecdysone indicate that the hormone causes an inhibition of release of NSM from the MNC

Fig 1 Schematic diagram of the proposed interactions between the cerebral neurosecretory system and ecdysone during moulting in *Rhodnius*

coupled with stimulation of synthesis of new material⁷. Hence the effect of ecdysone on the MNC is apparently a negative feedback on release of NSM coupled with a stimulation of synthesis. Such an arrangement possesses striking functional similarities with the so-called 'short-loop' feedback mechanisms familiar (though controversial) in the regulation of the anterior pituitary whereby adenohypophyseal hormones influence production of their respective releasing factors in hypothalamic nuclei^{10,11}. The adenohypophysis and prothoracic gland are comparable as endocrine effectors of neurohormones¹² and it now seems that both glands provide the neurosecretory cells which regulate them with humoral feedback information.

The following scheme suggests how this feedback mechanism may operate in the normal moulting cycle of *Rhodnius* (Fig 1). Abdominal distension following feeding excites stretch receptors which discharge to the brain^{4,13}, providing presynaptic stimulation of the MNC and causing release of NSM⁷. The principal effect of the NSM is to stimulate production of ecdysone which promotes moulting in the tissues. Ecdysone seems to have a positive feedback on its own production^{14,15}, thereby amplifying the hormonal instructions from the brain. By the time ecdysone production peaks, release of 'brain hormone' is greatly reduced⁵ and the head is no longer necessary for moulting⁴. This decline in 'brain hormone' release is not due merely to a decline in the afferent stimuli favouring release, however,

Table 1 Effects on the MNC of premature exposure to ecdysone by parabiosis and by injection of synthetic hormone

Cell type	Type 1	Type 2	Type 2a	Type 3	Type 4	Total
Normal insect at day 8	4.2 ± 0.2	6.4 ± 0.2	0.2 ± 0.1	3.2 ± 0.3	5.0 ± 0.0	19.1 ± 0.3
Parabiosis (from 1 to 8 d) to a decapitated insect producing ecdysone	1.8 ± 0.2	2.6 ± 0.3	5.8 ± 0.5	3.2 ± 0.4	5.3 ± 0.1	18.7 ± 0.4
Ecdysterone (1 µg) injected at days 1 and 3	2.1 ± 0.5	4.1 ± 0.6	6.4 ± 0.5	2.6 ± 0.3	5.0 ± 0.1	20.3 ± 0.6

Figures are the mean number (± s.e.) of the five cytologically distinct cell types present in the MNC on day 8 after feeding, following the treatments described

because the time course of the process is influenced by ecdysone, the increasing titre of which seems to act back on the brain where release is inhibited and synthesis of NSM promoted. Indeed, an engorged *Rhodnius* remains noticeably distended for several weeks after feeding and the abdominal stretch receptors show a maintained adapted discharge rate¹⁶. It follows that at the time when the effects of ecdysone on the MNC normally become apparent (at 6–8 d), neural stimuli favouring release would still be arriving at the brain and the neurosecretory system would have to 'decide' between these conflicting neural and humoral instructions. The significance of the MNC as the 'final common path'¹⁷ of this process of neuroendocrine integration is most obvious in the experiments where ecdysone is provided 1 d after feeding, the rate of release of NSM in response to the neural stimuli is normally very high at this time⁵ but these stimuli cease to be effective when ecdysone is provided. This suggests that the feedback effect of ecdysone may occur either directly on the MNC or on neurones concerned with their presynaptic control, to reduce their sensitivity to presynaptic stimulation (Fig. 1). Indeed, there is some evidence that ecdysone directly depresses the firing rate of insect central neurones¹⁸. Similarly, the effect of adenohypophyseal hormones on the hypothalamus may be on the cells elaborating releasing factors or on neurones controlling them^{10,11}. Steroid sensitivity is apparently not a general property of central neurones, however, as not all hypothalamic neurones show it¹⁹ and in *Rhodnius* some of the cell types in the MNC respond to ecdysone while others seem to be unaffected (Table 1).

The reported inhibition of release of NSM at the 'critical period' is thus explicable in terms of selective modulation of central excitability by ecdysone, the simultaneous promotion of synthesis by ecdysone must involve other mechanisms which are provisionally assumed to include direct action of ecdysone on the MNC (Fig. 1). Although tentative because of the indirect nature of the evidence, the above scheme illustrates the mutual interdependence of insect hormones and the importance of neuroendocrine integration in their regulation.

I thank the Science Research Council for financial support.

Role of growth hormone in glycosaminoglycan synthesis by articular cartilage

LITTLE is known of the factors which regulate the turnover of the glycosaminoglycans, chondroitin sulphate and keratan sulphate,

in articular cartilage. Studies using costal cartilage¹ suggest that growth hormone (somatotrophin) has little direct action on glycosaminoglycan synthesis. Instead its action is thought to be mediated by the liver² which produces a different hormone, somatomedin, previously known as 'sulphation factor' because it stimulates the incorporation of ³⁵SO₄ into costal cartilage.

These conclusions are not necessarily true for articular cartilage. Denko and Bergenstal³ found differences between the incorporation of ³⁵SO₄ by costal cartilage and the cartilage of the tibial 'cap' in young rats. For example, following hypophysectomy, incorporation of ³⁵SO₄ by costal cartilage was depressed, but no change was observed for the tibial 'cap'.

That such differences should exist is not surprising, for although costal and articular cartilage resemble each other in structure, their function is entirely different. Furthermore, it is necessary to distinguish between articular cartilage and epiphyseal cartilage and the tibial 'cap' is unsatisfactory because it includes both.

We carried out two separate experiments to investigate the action of growth hormone on articular cartilage. *In vitro* studies enabled us to investigate the action of bovine growth hormone on bovine articular cartilage. Of necessity we had to use smaller animals for *in vivo* studies and we selected the rat, as bovine growth hormone is known to be biologically active for this species.

In the *in vivo* studies bovine growth hormone (NIH-GH B17) was given by subcutaneous injection for 14 d to mature male rats. During this treatment these 'plateaued' rats showed a gain in weight, compared with a control group which showed a slight fall. After 14 d, each animal was given 100 μ Ci ³⁵S-labelled Na₂³⁵SO₄ by intraperitoneal injection and killed 24 h later. The distal femora and proximal tibiae from each animal were decalcified and sections through their joint surfaces examined by the method of autoradiography. There was no detectable difference between the group treated with growth hormone and the controls with regard to labelling of the articular cartilage. Slivers of articular cartilage were cut from the proximal humerus of the same two groups of animals for quantitative study. These samples were weighed by an electrobalance and dissolved by boiling with 23 M formic acid, radioactivity was determined using a Packard Tri-Carb liquid scintillation counter. Counts for each sample were divided by their weight to give specific activity. This showed no significant difference between the two groups.

In such an *in vivo* study, it is not possible to distinguish between the effects of growth hormone itself and somatomedin which is presumably released by the liver in response to growth hormone injections. These factors were investigated separately *in vitro*, using a medium containing somatomedin prepared by previous incubation of growth hormone with liver slices⁴. Optimal conditions for glycosaminoglycan synthesis were obtained by organ culture of bovine articular cartilage in 20% oxygen and using a chemically defined medium⁵. The articular cartilage was obtained from 6-month-old calves, being from the same species as the growth hormone (NIH-GH B17).

Organ culture of articular cartilage was performed simultaneously using eight culture chambers, divided into four groups, differing only in the nature of the culture medium⁴. Group A, Eagle's MEM, group B, Eagle's MEM containing bovine growth hormone (concentration 1.0 μ g ml⁻¹), group C, Eagle's MEM incubated beforehand with liver slices, group D, Eagle's MEM plus bovine growth hormone (concentration 1.0 μ g ml⁻¹) incubated beforehand with liver slices.

Four samples of cartilage, each about 1 mg dry weight, were removed from each chamber after 24, 48 and 72 h. This amount of material is adequate for fractionation of glycosaminoglycans on the microscale⁶.

Two separate experiments were performed, using different donor animals to provide the articular cartilage. Samples were pooled from each of the groups, A, B, C and D, so that the final values represent analysis of 16 separate pieces of articular cartilage for each group.

Table 1 Specific activities of fractions from CPC cellulose microcolumns

Eluting solution	24 h				48 h				72 h

0.4 M MgCl ₂	882	479	415	505	588	134	150	201	454	276	237	260
0.45 M MgCl ₂	869	495	309	474	433	111	114	115	492	198	208	189
0.5 M MgCl ₂	1,377	1,075	472	472	427	120	134	100	506	196	325	263
0.6 M MgCl ₂	4,305	2,213	1,794	2,215	778	165	262	100	499	228	574	676
2.0 M MgCl ₂	1,585	2,102	2,430	2,144	364	125	556	983	259	075	510	948
6 M HCl	375	238	342	263	106	283	126	046	228	0	279	318
Total chondroitin sulphate	1,290	828	533	630	689	245	185	131	716	315	337	332
Highly sulphated keratan sulphate	954	828	1,233	895	273	170	354	522	240	330	388	672

The values shown are means of two calculations of specific activity (c.p.m. divided by hexosamine content in μg) for each fraction eluted from the CPC cellulose microcolumns. The different experimental groups, A, B, C and D are explained in the text. Chondroitin sulphate of increasing chain length is eluted by the 0.25 M to 0.6 M MgCl₂ solutions and highly sulphated keratan sulphate by the 2.0 M MgCl₂ and 6.0 M HCl fractions. The mean specific activity for these two glycosaminoglycans was determined by dividing the sum of counts for each of their fractions by the sum of the hexosamine content of these fractions.

After their removal from the culture chambers, the cartilage samples were incubated in Tyrode's solution, containing $0.5 \mu\text{Ci } ^{35}\text{SO}_4 \text{ ml}^{-1}$. After 1 h they were removed and further enzyme activity prevented by immersion in monoiodoacetic acid. The samples were washed to remove unbound $^{35}\text{SO}_4$, dehydrated in acetone and dried in air to constant weight. Following digestion by papain, the glycosaminoglycans were fractionated on cetyl pyridinium chloride (CPC) cellulose microcolumns⁶, using eluting solutions as shown in Table 1. All analyses were performed in duplicate. Chondroitin sulphate is eluted by the magnesium chloride solutions 0.25 M to 0.6 M and highly sulphated keratan sulphate by 2 M magnesium chloride and 6 M HCl. The first fraction obtained by elution with CPC contains keratan sulphate with glycopeptides and some unbound sulphate. These components were separated using ecteola cellulose microcolumns⁷, keratan sulphate being eluted by 0.4–1.2 M NaCl solutions. Characterisation of these fractions from calf articular cartilage has been previously reported using electrophoresis on cellulose acetate membranes⁸. Each fraction

was divided into aliquots for determination of hexosamine content and scintillation counting.

The results shown in Tables 1 and 2 are indices of the synthesis rate of each fraction, that is, c.p.m. divided by the weight of hexosamine in micrograms ('specific activity').

The addition of growth hormone to the culture medium (group B) resulted in diminished incorporation of $^{35}\text{SO}_4$ for all fractions after each of the time intervals studied. This applies equally to all fractions of chondroitin sulphate (0.25 M to 0.6 M MgCl₂ fractions) and keratan sulphate (0.4 M to 1.2 M NaCl fractions plus the 6 M HCl fractions). A similar depression of $^{35}\text{SO}_4$ is seen for group D (previous incubation of medium with growth hormone plus liver slices), but with the exception of highly sulphated keratan sulphate (2.0 M MgCl₂ and 6 M HCl fractions from the CPC columns). After 48 and 72 h, this highly sulphated keratan sulphate showed an enhanced incorporation of $^{35}\text{SO}_4$, presumably in response to somatomedin, as no such change was seen for group B or group C (previous incubation with liver slices only).

The design of this experiment was very similar to that of

Table 2 Specific activities of fractions from ecteola cellulose microcolumns

Eluting solution	24 h				48 h				72 h			
	A	B	C	D	A	B	C	D	A	B	C	D
H ₂ O	0	0	0	0	0	0	0	0	171	900	0	173
0.02 M HCl	0	0	0	0	066	0	0	0	1,928	354	0	040
0.3 M NaCl	829	477	303	224	1,106	398	086	188	2,538	1,589	347	484
0.4 M NaCl	1,339	813	422	236	2,193	586	353	375	2,519	1,047	384	413
0.5 M NaCl	729	717	271	057	1,450	329	176	240	1,251	466	228	294
0.6 M NaCl	362	217	0	0	142	167	074	099	443	148	053	115
0.7 M NaCl	141	030	0	0	179	0	0	0	204	0	072	034
0.8 M NaCl	117	211	0	0	121	0	0	0	060	0	0	074
1.2 M NaCl	0	0	0	0	0	0	0	0	0	0	0	0
6 M HCl	0	0	0	0	0	0	0	0	0	0	0	0
Total keratan sulphate	493	298	124	062	708	157	092	109	1,210	402	169	197

The values shown are means of two calculations of specific activity for each fraction eluted from the ecteola cellulose microcolumns on refractionation of the CPC fractions obtained from the CPC cellulose microcolumns. Keratan sulphate is eluted by the 0.4 M to 1.2 M NaCl fractions and a mean specific activity was determined by dividing the sum of the counts for these fractions by the sum of their hexosamine content. Unbound $^{35}\text{SO}_4$ was removed from the ecteola cellulose columns by previous incubation with 0.1 M NaCl, repeated six times to give six fractions which had no significant hexosamine content. The zero for some of the fractions shown in this table represents a count below that of a standard blank salt solutions of the same molarity.

McConaghey⁴, who found that incorporation of ³⁵SO₄ by costal cartilage was slightly increased by the same purified growth hormone and markedly increased by somatomedin, prepared using liver slices. It is clear that articular cartilage behaves quite differently in its response to growth hormone, which, *in vitro*, depresses glycosaminoglycan synthesis. The response of articular cartilage to somatomedin was similar to that of costal cartilage only for highly sulphated keratan sulphate. It is very likely, however, that the medium used in group D still contains growth hormone not metabolised by the liver slices. This residual growth hormone could have obscured the action of somatomedin on the synthesis of chondroitin sulphate and keratan sulphate.

Whatever the effect of somatomedin, there can be no doubt that growth hormone itself has a direct action on articular cartilage *in vitro*. That action is to decrease glycosaminoglycan synthesis.

Bovine growth hormone was a gift from Dr Wilhelm, National Institutes of Health.

Purification of human uterine progesterone receptor

It is now generally accepted that before the physiological response to the androgens¹, oestrogens², glucocorticoids³ and progesterone⁴⁻⁷ can be manifested, these hormones must complex with specific receptors in their target tissue. Since progesterone is important both in the mechanisms associated with transport of the ovum through the oviduct^{8,9} and in preparing the endometrium for implantation of the blastocyst¹⁰, a greater understanding of the action of the hormone-receptor complex at the molecular level will lead to a more detailed knowledge of the mechanisms involved in reproductive biology. This understanding may be utilised to develop new contraceptive methods and to investigate the genesis and treatment of endometrial adenocarcinoma.

To study the molecular events associated with the function of progesterone and to determine the topography of the receptor site, it is necessary to obtain the receptor-hormone complex in a pure form. We report here the isolation and purification of the progesterone receptor from human uterus. A similar receptor has also been studied from the human oviduct (C. A. I., unpublished), and translocation and binding to oviduct nuclei has been demonstrated. Purification was achieved using a combination of ammonium sulphate fractionation, affinity chromatography and ion-exchange chromatography. The overall purification from the 105,000g supernatant fraction from a

crude tissue homogenate is approximately 8,000-fold. Since the cytosol fraction is an approximately fivefold purification over the whole cell we estimate a 40,000-fold purification for the progesterone receptor with respect to the intact cell. The concentration of progesterone binding sites in the crude cytosol is 3×10^{-8} M per mg protein. The pure receptor sediments at 3.7S on sucrose gradient centrifugation and migrates as a single band of molecular weight 110,000 on SDS polyacrylamide gel electrophoresis. It has not yet been determined, however, whether more than one subunit of the same molecular weight is present. These data will be reported in detail elsewhere.

The specificity of the ammonium sulphate-purified receptor (Table 1) showed the following relative affinities: progesterone > 11-desoxycorticosterone > 5 α -dihydroprogesterone > 5 β -

Table 1 Comparisons of hormone binding to the progesterone receptors from human, chick and hamster target tissues

	Human	Chick ⁸	Hamster ⁹
Progesterone	100	100	100
5 α -Dihydroprogesterone	12	86	20
5 β -Dihydroprogesterone	6	15	4
11-Desoxycorticosterone	28	94	64
Substance S	7	7	11
Corticosterone	5	3	3
Cortisol	<1	<1	<1
Testosterone	2	5	4
Oestradiol	<1	<1	1

Tissues were segmented and rinsed in ice-cold saline solution, weighed and homogenised in four volumes (w/v) TESH buffer, 0.01 M Tris-HCl, 1.0 mM Na₂EDTA and 0.012 M thioglycerol (pH 7.4). The homogenate was centrifuged at 27,000g for 10 min and the supernatant was re-centrifuged at 105,000g for 1 h to obtain the cytosol fraction. Glycerol was added to the buffer to a concentration of 40% when human uterine tissue was used. For the competition assay a series of tubes were prepared containing cytosol, ³H-progesterone and unlabelled steroid competitors in TESH buffer. The assay tubes were incubated at 0°C for 16-20 h and ³H-progesterone binding was measured by charcoal adsorption. Each assay point was determined twice. A standard curve for the competition of unlabelled progesterone was included in each assay using five progesterone concentrations usually in the range 3.5×10^{-9} to 7.1×10^{-7} M. Four or five concentrations of each competitor were tested using a range between 3×10^{-9} and 7×10^{-7} M. The competitor concentrations were chosen to provide a linear portion on a semi-log plot which would cross the point of 50% competition. From this plot, the concentrations of unlabelled progesterone and of steroid competitors which reduced ³H-progesterone binding by 50% were determined. These quantities were converted to molar concentrations and the effectiveness of the competition was established using the ratio: unlabelled progesterone concentration for 50% competition/competitor concentration for 50% competition. This ratio was multiplied by 100.

dihydroprogesterone > corticosterone > testosterone >> oestradiol > cortisol. The relative affinity of cortisol shows that the most probable contaminant, cortisol binding globulin, is absent. A comparison of these specificities with those obtained from crude cytosol receptors of chick oviduct¹¹ and hamster uterus¹² (Table 1) shows that the partially purified human uterine receptor is the more selective. It was not possible to determine specificity by competitive assay for progesterone binding sites at subsequent steps in the purification since the receptor is saturated with labelled progesterone during its elution from the affinity column. Because of the lability of the receptor, it has not yet been possible to remove the hormone and retain the native activity of the receptor. Scatchard analysis shows, however, that only molecules containing binding sites specific for progesterone are retained by the affinity resin.

The affinity resin was prepared by coupling denatured bovine serum albumin to cyanogen bromide-activated Sepharose¹³ followed by reaction with 11-desoxycorticosterone hemisuccinate in the presence of 1-ethyl-3-(3-dimethylaminopropyl)

Fig. 1 Sucrose gradient ultracentrifugation analyses of ^3H -progesterone-treated Δ , human uterine cytosol; \bullet , receptor obtained after affinity chromatography; \circ , nuclear extract (0.4 M KCl) from human oviduct. Samples (0.2 ml) were layered on linear 5–20% (w/v) sucrose gradients made up in 10% glycerol, containing 0.05 M Tris, 1 mM EDTA and 0.01 M thioglycerol at pH 7.5, and then centrifuged for 17 h at 216,000g. ^{14}C -ovalbumin (3.7S) was used as a sedimentation standard.

carbodiimide hydrochloride. After thoroughly washing each millilitre of resin with 200 ml dioxane followed by 21.80% methanol/water, the capacity of the resin is 0.21 nmol per ml packed resin and its dissociation constant for the receptor is 10^{-9} M (the dissociation constant of progesterone for its receptor is $\sim 10^{-9}$ M). Cortisol (10^{-6} M) was added to the ammonium sulphate-precipitated receptor prior to incubation with the affinity resin, so that binding of the resin to corticoid receptors and possibly certain steroid metabolising enzymes would effectively be negated. After incubation for 12 h at 2°C each millilitre of resin was washed with 200 ml of buffer containing a high salt concentration (0.4 M KCl) to remove relatively loosely associated proteins. Elution of the receptor in batches was accomplished by incubating at 20°C for 30 min in the presence of excess labelled progesterone. The macromolecular bound hormone was isolated by gel filtration and applied to a DEAE-cellulose column and eluted with a salt gradient. The receptor-progesterone complex was eluted in 0.2 M KCl, dialysed, lyophilised and applied to an SDS polyacrylamide gel. Electrophoresis revealed a single band of molecular weight 110,000.

The dissociation constants for progesterone ($K_D \sim 10^{-9}$ M) and the relative affinities of various steroids for the crude and the partially purified receptor are almost identical (Table 1). The crude, the partially purified and the pure receptor all show

similar physical properties: the macromolecule sediments at 3.7S (Fig. 1) and is eluted from phosphocellulose by 0.17 M KCl, from DEAE-cellulose by 0.2 M KCl. A nuclear extract obtained after preincubation of nuclei with labelled receptor also sediments at 3.7S (Fig. 1). Collectively, the data therefore confirm the integrity of the pure progesterone receptor.

Incubation of human oviduct nuclei with receptor- ^3H -progesterone complex, both at 0°C and 37°C, showed translocation was occurring. Extraction of the nuclei with a high salt buffer (0.4 M KCl) followed by sucrose gradient centrifugation of the extract demonstrated macromolecular bound hormone sedimenting at 3.7S. It is not surprising that nuclear binding occurs at both temperatures since it has been shown previously in the chick oviduct system that activation of the progesterone-receptor complex by ammonium sulphate alone is sufficient to effect translocation and binding at 0°C (ref. 14). Human oviduct rather than endometrial nuclei were used because of the greater amount of tissue available combined with ease in obtaining pure nuclei.

For the first time, therefore, we have demonstrated the purification of a human uterine progesterone receptor (Table 2), together with its translocation and binding to human target nuclei. Characterisation of the receptor site may enable us to design specific agents to block progesterone binding at this site thus precluding the physiological action of this hormone. In addition, we now have the opportunity to study in detail the mechanism of action of progesterone.

This research was supported by the Population Council, the Ford Foundation, the NIH Population Center at Baylor College of Medicine and a Population Council Fellowship to C.A.I. We thank Mr L. V. Echeverria for technical assistance, the surgical staff of the Department of Obstetrics and Gynecology, Baylor College of Medicine for supplying tissue, and St Luke's Episcopal Hospital for allowing us to carry out this work.

Is potassium conductance of cardiac Purkinje fibres controlled by $[Ca^{2+}]_i$?

ELEVATED extracellular Ca^{2+} concentration¹, prolonged treatment with high doses of cardiac glycosides², and metabolic inhibition³ shorten the action potential of cardiac muscle. In these conditions the intracellular free Ca^{2+} may be increased and an increase in intracellular Ca^{2+} could produce shortening of the action potential either by affecting the Ca^{2+} inward current or by increasing the potassium permeability⁴. The latter mechanism has been observed in red blood cells⁵ and in the neurones of some species⁶⁻⁸. Here I give the results of studying the effect of iontophoretically injected Ca^{2+} in cardiac Purkinje cells. Such injection led to membrane hyperpolarisation and considerable shortening of the action potential, suggesting that the level of intracellular free Ca^{2+} can affect the potassium permeability in cardiac muscle.

The diffusion coefficient of radiocalcium in skeletal muscle fibres seems to be 100 times less than that in water⁹. This suggests that an effect produced by the electrophoretic injection of Ca^{2+} can only be observed within a small region round the injection site. To ensure that the tip of the microelectrode recording resting and action potentials was placed in the region of elevated $[Ca^{2+}]_i$, in most experiments a single electrode filled with 1 M $CaCl_2$ was used both for injection and for recording¹⁰. A second intracellular electrode (filled with potassium citrate) served to stimulate the preparations at a rate of 15 min⁻¹.

In Fig 1*b*, the first action potential (AP) illustrates the control values (resting potential (V_m), -76 mV, plateau potential, -16 mV, duration of the action potential (APD), 635 ms). Thereafter an inward directed current pulse (Fig 1*a*) injected about 0.1 μ Ci from the Ca^{2+} filled electrode, this current depolarised the preparation to +20 mV for 1 s. When the injecting current was switched off the membrane re- and hyperpolarised (V_m -95 mV). One second after injection, the second AP was elicited. The plateau began at a potential more positive (-7 mV) and was shorter than that of the control, the APD being reduced to 380 ms. From the plateau, the membrane repolarised (with almost unchanged speed) to a high negative (-91 mV) diastolic potential. Within the next 2 s V_m declined like an enhanced pacemaker potential and 5 s after injection both V_m and the AP were almost identical with the control.

It could be argued that injecting the current produces not only an increased $[Ca^{2+}]_i$, but also a strong activation of the potassium conductance g_K due to the large depolarisation⁷. To exclude the latter possibility, in five experiments the Ca^{2+} injecting electrode was replaced by a double-barrelled electrode, one side filled with $CaCl_2$, the other with 3 M KCl. The current was injected between the $CaCl_2$ barrel and second intracellular microelectrode filled with potassium citrate without an earth

Fig 1 Effect of intracellular iontophoretic injection of +0.1 μ Ci (a) from a microelectrode filled with 1 M $CaCl_2$ solution on transmembrane resting and action potential (b). Experiment on sheep Purkinje fibre, superfused by oxygenated Tyrode solution containing (mM): 150 NaCl, 4 KCl, 0.9 $CaCl_2$, 1 $MgCl_2$, 5 glucose and 10 Tris-maleate buffer, pH 7.4, temperature 37°C. Chart recording, the action potential overshoots are attenuated. The depolarisation during injection was measured by the non injecting K-citrate electrode.

(battery-driven current pump). A third intracellular microelectrode was used for stimulating the preparation. A current of +100 nA out of the $CaCl_2$ capillary, hyperpolarised the membrane from -85 to -92 mV and 0.8 s after the end of injection the APD was shortened from 540 ms (control) to 320 ms. If, after injecting the Ca^{2+} , the membrane was clamped to the control level (-85 mV) for 500 ms, nearly the same reduction of APD (from 540 to 310 ms) was observed.

The resistance of the electrode increased during injection. When more than 0.5 μ Ci were applied the current frequently decreased (R_{ei} more than 800 M Ω , saturation of the current pump⁷). It was then difficult to separate the Ca^{2+} induced hyperpolarisation from an increase in tip potential. The stability of the electrodes was better when they were filled with a Ca^{2+} -EGTA buffer solution (electrodes filled with 0.09

Fig. 2 Transmembrane action potentials. Each panel shows photographically superimposed chart recordings of control action potentials (trace 1 in *a*, *b*) and after iontophoresis *a*, Injection of +0.3 μ Ci from a microelectrode filled by Ca^{2+} -EGTA buffer solution Tyrode with $K_o = 5.4$ mM. Action potential 0.4 s (trace 2), 0.8 s (trace 3) and 2.5 s (trace 4) after the end of the injecting current pulse. *b*, Injection of +0.3 μ Ci as in *a*, but at a lower K^+ concentration (4 mM) in the Tyrode solution. Action potential 0.8 s (trace 2), 1.5 s (trace 3) and 3 s (trace 4) after the end of the injecting current pulse.

M $Ca(OH)_2$, 0.1 M EGTA, and 0.1 M Tris, resistance of the electrodes 120-150 M Ω)⁸.

Figure 2*a*, trace 2, shows an AP 0.4 s after injection of +0.3 μ Ci from an electrode filled with Ca^{2+} -EGTA buffer. The injection caused hyperpolarisation and a reduction of the APD from 550 ms (trace 1, control) to 250 ms (trace 2). The configuration of the AP was altered similar to that in Fig. 1. For constant charges of the injected Ca^{2+} , the shortening of the APD was more pronounced the shorter the delay between injection and AP. Thus, 0.8 s after injection, the APD was shortened only by a small amount (Fig 2*a*, trace 3) and 2.5 s after injection the AP was identical to the control (Fig. 2*a*, traces 1 and 4). This normalisation of the APD could be fitted by a single exponential. From 22 experiments, a time constant of 0.5 ± 0.2 s was calculated for the decay.

In Fig 2*b* the Tyrode solution contained a K^+ concentration somewhat smaller (4 mM) than in Fig 2*a* (5.4 mM). Injection of +0.3 μ Ci produced hyperpolarisation of V_m and shortening of APD as in Fig. 2*a*. Both effects however, were more pronounced and lasted longer (time constant for the decay, 1.0 ± 0.2 s, $n, 15$).

When the time interval between injection and AP was constant, the APD was shorter the larger the amount of the injected Ca^{2+} . Currents less than 10 nA did not affect the APD, independent of their duration (presumably the cell can rapidly extrude or sequester such an amount). The formulation of a quantitative relationship was not, however, possible with the present data.

The shortening of the APD on the injection of Ca^{2+} could be explained by a reduction of the Ca^{2+} driving force diminishing

the slow inward current? Viewed in conjunction with the strong hyperpolarisation, however, the most likely explanation is that elevated $[Ca^{2+}]$, increased the potassium conductance g_K .

I thank Professors W Trautwein and K Peper and Dr T F McDonald for their advice. This work was carried out under the auspices of the Deutsche Forschungsgemeinschaft

Role of foetal adrenocorticotrophin during parturition in sheep

It is now well accepted that the lamb foetus plays an important role in the mechanisms which initiate its own delivery. This conclusion, is based on several experimental observations. Foetal hypophysectomy or adrenalectomy delays parturition^{1,2}, infusions of adrenocorticotrophin (ACTH) or cortisol, which is the major glucocorticoid in this species, will precipitate premature delivery when infused into the foetus³, normal delivery is preceded by an increase in the concentration of corticosteroids in the foetal blood^{4,5} and an increased production of cortisol by the foetal adrenal⁶.

The simplest hypothesis to explain these changes is that an increase in foetal pituitary secretion of ACTH stimulates the production of cortisol from the foetal adrenal. The cortisol is thought to act on placental enzyme systems to bring about several changes, in particular an increase in maternal plasma oestrogen concentrations^{7,8}, and maternal oestrogens have been shown to rise sharply in the last few hours before delivery⁹. This increase also occurs after the administration of ACTH or glucocorticoids to the foetus⁷.

The results obtained from the experiments involving foetal hypophysectomy, however, do not prove that an increased secretion of ACTH by the foetal pituitary is necessarily involved in the initiation of parturition. It is possible that foetal hypophysectomy may delay parturition by lowering foetal plasma ACTH concentrations and thus impairing adrenal maturation and the development of adrenal responsiveness to other stimuli of either foetal or maternal origin. These alternative explanations have been discussed in detail elsewhere⁶. The changes in foetal plasma corticosteroid and ACTH concentrations in the period before parturition have been studied in the foetal sheep using indwelling vascular catheters¹⁰. Foetal plasma ACTH concentrations were reported to be very labile, 100-1,800 pg ml⁻¹, and the authors concluded that when average values were considered there seemed to be a rise in ACTH during the last days before delivery. Sequential values from the same animal for more than three days were available in only two foetal sheep which were delivered vaginally and one of the two ewes was subjected to three bouts of experimental hypoxia. It therefore seemed important to obtain further data* from undisturbed foetuses during late gestation and parturition. The experiments reported here were carried out to relate changes in plasma ACTH and cortisol concentrations both to each other and to the timing of delivery.

Seven ewes with singleton pregnancies of 124-130 d gesta-

tional age were used in the present investigation. A foetal venous catheter was introduced into each leg through the lateral tarsal vein. Foetal blood samples were taken at least once daily, if obtainable, throughout the experimental period for the assessment of foetal condition as indicated by blood gas and pH analysis, but no samples for hormone estimations were taken for at least 48 h after surgery. In all samples analysed for ACTH and cortisol concentration, foetal pH was within the normal range (7.32-7.41) except for samples taken during the final stage of labour when the usual fall in foetal pH was observed. Blood gas tensions were normal. Foetal blood was taken into cold syringes, centrifuged immediately and the plasma stored at -20°C. All estimations were performed within 1 month of sampling. Total plasma corticosteroids were measured in most samples by competitive protein binding without chromatographic separation¹¹. Some samples taken from foetuses at different days before delivery were separated on a Sephadex LH20 system¹². When this was done, cortisol accounted for more than 80% of the total corticosteroids as measured by competitive protein binding irrespective of gestational age. This finding is in agreement with the pattern of steroid secretion found when foetal adrenals of different ages are incubated *in vitro*¹³. Corticosteroid concentrations have therefore been designated as cortisol in the present study. Plasma ACTH was measured by radioimmunoassay after extraction on to porous glass¹⁴. Plasma samples of 0.5-1.0 ml were extracted and Third International Standard ACTH (31WS)¹⁵ used as both standard (unlabelled) and iodinated (labelled) hormone.

Two foetuses were each sampled four times over 48 h on days 130-132 of gestation to obtain data on foetal plasma ACTH concentrations before they were used for a separate experiment. Four foetuses were sampled up to the spontaneous delivery of a live lamb (Fig 1). One further foetus was sampled every 6 h (0000, 0600, 1200, and 1800) for 4 d. A

Fig 1 Plasma cortisol (●) and ACTH (○) concentrations over the last 14 d of intrauterine life in four chronically catheterised foetal sheep. Although the foetal catheters were patent, it was impossible to obtain blood samples from S723 between 8 and 2 d before delivery. S681 delivered at 147 d gestational age, 11 d after catheterisation, S686 delivered at 133 d gestational age, 9 d after catheterisation, S710 delivered at 139 d gestational age, 11 d after catheterisation, S723 delivered at 151 d gestational age, 23 d after catheterisation.

total of 40 ml of blood was removed in this period and therefore blood loss may have been a contributory factor to the subsequent death of this foetus *in utero*. It was equally possible that death occurred *intra partum* as the increase in foetal plasma cortisol was followed by a rise in maternal plasma oestrogen concentration while the foetus was still alive.

In none of the five foetuses which were sampled sequentially was there any significant increase in foetal plasma ACTH before the preparturient rise in foetal plasma cortisol concentration. In three of the animals, plasma ACTH concentrations were low in the period up to 96 h before delivery (242.5 ± 18.4 pg ml⁻¹, mean \pm s.e.m., $n = 16$). Foetuses 686 and 681 were in this group. Mean plasma ACTH concentration in the other foetuses was 691.8 ± 127.3 pg ml⁻¹ ($n = 9$) in this same period (foetuses 723, 710). For all five foetuses the mean plasma concentration of ACTH for the period up to 4 d prepartum was 435.8 ± 67.6 pg ml⁻¹ ($n = 25$). In the two further foetuses sampled four times between 130 and 132 d, mean plasma ACTH concentrations were 177 and 203 pg ml⁻¹.

In contrast to the absence of an increase in foetal plasma ACTH before the prepartum rise in foetal plasma cortisol concentration, there was a pronounced increase in foetal plasma ACTH concentration in the last 24 h of foetal life. In one of the two foetuses which initially had a low plasma ACTH concentration (681) ACTH rose to 882 pg ml⁻¹ in the last 6 h of intrauterine life. In the other foetus (686), ACTH rose to 1,680 pg ml⁻¹ 40 min before delivery. There was a further rise to 2,380 pg ml⁻¹ 5 min before delivery. Although strong, coordinated uterine contractions only occur in the last 6 h or so of gestation in the ewe, contractions are gradually increasing in frequency and amplitude over the last 24 h of foetal life. It may be that stimulation of the foetus by uterine contraction is one of the causes of the increase in plasma ACTH that occurs at this time. The ACTH released during this period is probably the cause of the rapid rise in cortisol concentration which occurs in the last few hours of foetal life. Immediately after delivery plasma ACTH reached 3,001 and 1,948 pg ml⁻¹ in two lambs (681 and 723).

We would emphasise that results which contain only single daily observations for foetal plasma ACTH must be viewed with caution for two reasons. First, it is well known that in the adult ACTH is secreted in an episodic manner¹⁶. The results obtained from the foetus which was sampled every 6 h showed that there were changes in both foetal plasma cortisol and ACTH concentrations during the day and there was some indication of a nyctohemeral rhythm in circulating concentrations. It may be that the total daily secretion of ACTH by the foetus increases before foetal cortisol rises. Such a mechanism would explain the increased sensitivity of the foetal adrenal which occurs just before parturition¹³, as well as the increased secretion of foetal corticosteroids^{6,13}. To investigate this possibility it will be necessary to sample the foetus more frequently. To avoid haemorrhagic stress an increase in the frequency of sampling will require the availability of the cytochemical assay for ACTH¹⁷. Second, in the adult mammal it is known that cortisol will exert a negative feedback on ACTH secretion at both physiological and pharmacological concentrations¹⁸. Thus, the high plasma corticosteroid concentrations immediately before delivery may be exerting a negative feedback action on ACTH secretion. The final level of ACTH secretion will depend on the summation of any such negative feedback and the positive drives on the hypothalamo-hypophyseal-adrenal axis.

In conclusion, simultaneous measurements of plasma ACTH and cortisol concentrations have been made on sequential blood samples obtained from seven chronically catheterised foetal sheep. Five of these foetuses were sampled sequentially for several days before delivery. The basal ACTH concentrations varied between animals. This variation in basal concentration cannot at present be explained. On the basis of the present data there was no evidence for an increase in foetal plasma ACTH before the preparturient rise in foetal plasma cortisol.

Novel 4-hydroxycoumarin anticoagulants active against resistant rats

FIELD populations of common rats (*Rattus norvegicus*) resistant to anticoagulant rodenticides (for example, Warfarin) have appeared¹ in Scotland, Denmark, England and Wales, and more recently on the American continent. This resistance seems to be associated with a reduction in the efficiency of vitamin K metabolism² and is an inheritable factor controlled by a single dominant autosomal gene. Various theories have^{1,2} been advanced to explain the underlying mechanism. Resistance to other anticoagulants has now appeared, that to coumatetralyl being the least effective¹.

Reduction of the carbonyl group of Warfarin and replacement of the terminal methyl group with various substituted phenyl groups produces compounds showing increased anticoagulant activity^{4,5}. We have synthesised compounds of this type (compounds 1 and 2, Table 1) and have found that activity was only demonstrated in normal rats and not in the resistant strain.

Comparison of the structures of Warfarin and coumatetralyl suggested that the activity of the latter in resistant rats might be due to the manner in which, in the tetralin moiety, the four carbon atoms of the saturated ring are held adjacent to the unsaturated ring, whereas the four carbon atoms in the side chain of Warfarin can assume many conformations other than those adjacent to the benzene ring. Compounds were therefore synthesised containing substituted phenyl groups attached by a three carbon chain to a 4-hydroxy coumarin moiety, the three carbon chain being part of a saturated ring fused to a benzene ring. Examples of such are the 3-(3-*p*-substituted-1,2,3,4-tetrahydronaphth-1-yl) 4-hydroxycoumarins and related compounds shown in Table 1.

Several conclusions may be drawn from these results

Prothrombin ED₅₀ mg per kg of compound given in three daily doses predicted to increase prothrombin time (as measured by the one stage method of Quick) from a resting value of 16 s to 112 s on the fourth day. Male rats were used throughout. Diphacinone, chlorophacinone, coumatetralyl, S(−) Warfarin and R(+) Warfarin give prothrombin ED₅₀s of 0.22, 0.22, 0.31, 0.30 and 3.3 mg kg⁻¹, respectively in Wistar rats and of ~50.0, >20.0, ~4.4, >50 and >50 mg kg⁻¹ respectively in resistant rats. Resistance factor = ratio of prothrombin ED₅₀s for resistant and normal rats. Diphacinone, chlorophacinone, coumatetralyl, S(−) Warfarin and R(+) Warfarin thus have factors of ~227, >90, ~14, >166 and >15, respectively. Bait trial: rats were exposed to the test baits with no alternative food for 10 d, mortalities were recorded up to 14 d. Female Welsh strain homozygous resistant rats were used throughout. Diphacinone, S(−) and R(+) Warfarin did not cause death at 250 p.p.m. and chlorophacinone and coumatetralyl gave 20% and 40% mortality, respectively, at this concentration. The melting point of compound 1 was 200–201°C, satisfactory analytical data were obtained for the other compounds whose preparation will be described elsewhere. Compounds 3–24 are two component mixtures (thin layer chromatography, TLC) of what are believed to be *cis* and *trans* isomers. In two cases (compounds 10 and 12) the slower running isomer (TLC) was shown to be two to four times as active as the faster running isomer. Since the proportion of the slower running isomer in the mixtures is >50% (TLC) this is unlikely to significantly alter the structure-activity relationships. Patent applications are pending on the 3-(3-*p*-substituted-phenyl-1,2,3,4-tetrahydronaphth-1-yl) 4-hydroxycoumarins.

The substituent in the *para* position of the phenyl group may vary in size with little effect on potency (compounds 4–8) although such limitations are indicated, for example, when the *para* substituent is methyl or tetralyl (compounds 3 and 18), anticoagulant activity is lost. A further aromatic ring joined either directly to the *para* position of the phenyl group (compound 10), or to the *para* position by oxygen or methylene bridges (compounds 11 and 17) seems to be advantageous. The most active compounds contain a *para* halogenophenyl group either joined directly to the *para* position of the phenyl group or joined to this position by an oxygen bridge (compounds 12–14).

A requirement for anticoagulant activity in either strain of rat seems to be a lipophilic group in the *para* position of the phenyl group, suggesting that the substituted phenyl group is providing a point of attachment to a lipophilic site to which Warfarin and other anticoagulants do not bond strongly. The high activity exhibited when the phenyl group contains *para* substituents with somewhat less lipophilic character (compounds 15 and 16) infers that electronic effects may also play some part. Variations in activity, however, do not parallel those reported for the series obtained by replacing the terminal methyl group of Warfarin alcohol by substituted phenyl groups⁴. Substitution in the 7 position of the tetralin ring reduces or has little effect upon activity (compounds 19 and 20). Replacement of the tetralin moiety by chroman or indanyl rings (compounds 21–25) reduces activity and increases resistance. The angle which the phenyl group makes with the indanyl group (compound 25) differs markedly from that made with the tetralin group (compounds 3–20), this may be responsible for the loss of activity.

Bait trials show good agreement with the prothrombin estimations, compounds with the lowest prothrombin ED₅₀ generally being the most active. The indications are that the new materials are well absorbed in the gut and are promising rodenticides. It is interesting to compare kills of resistant rats with those obtained at considerably higher concentrations with the standard anticoagulants (see notes to Table 1).

Tests with two of these compounds (10 and 13) indicate that they act in the same manner as Warfarin (M R H, unpublished) in that they are not classic competitive inhibitors of vitamin K₁. This contrasts with 2-chloro analogue of this vitamin which is also somewhat effective in resistant rats⁶, presumably because it affects a site other than that attacked by Warfarin and is not therefore involved in the resistance mechanism.

One of these compounds (10) has been tested in the field against wild rat infestations resistant to normal anticoagulants, providing control in baits containing only 0.005% (M R H and B D Rennison, unpublished).

We thank the staff of the Pest Infestation Control Laboratory of the Ministry of Agriculture for providing our breeding stock of resistant rats, advice and encouragement.

Thermal transitions in collagen and the preferred temperature range of animals

We have shown^{1–3} that the melting point of the molecular collagen of both homeothermic land poikilothermic animals correlates with the upper limit of their range of preferred temperatures (the range of temperatures they will voluntarily tolerate in their natural environment). We now report that for some poikilotherms the lower limit of the range of preferred temperatures also correlates with certain thermal properties of their collagen.

This conclusion was derived from an examination of the mechanical properties of earthworm (*Allolobophora caliginosa*) cuticle and jellyfish (*Aurelia coerulea*) connective tissue when these are heated in physiological saline (0.9% NaCl). Native tissues were used because the properties of collagen are best studied in a condition as close as possible to that in which they exist in nature. Such studies complement and indeed extend work involving purified and soluble collagens.

Fig. 1 Diagram defining thermal transitions in a sample immersed in 0.9% NaCl. The ordinate represents the property observed as temperature is increased. The transitions A and B are defined as points of deviation from linearity. T_S is the familiar shrinkage temperature, T_A and T_B are discussed in the text.

The cuticle of the earthworm was removed from an animal which had been killed by holding at 0°C overnight, and this cuticle formed an ideal sample (1–2 μ m thick \times 10 cm long) for direct length measurements as the temperature was varied. The ends of the specimen were clamped together at one end after looping through a glass ring of sufficient mass to just keep the sample straight. Length measurements were made

Fig. 2 A length–temperature curve for a freely suspended sample of the cuticle of earthworm *A. caliginosa* in NaCl. The transitions A and B are indicated by arrows at 7°C and 25°C, respectively. T_S takes place at \sim 35°C.

with a cathetometer. As the applied stress was virtually zero, this experiment amounts to one-dimensional dilatometry.

The jellyfish samples were cut from the bell of the animal and stored in an acetone-water mixture until required. They were then washed and soaked in 0.9% NaCl overnight, by which time they had the appearance of fresh material. In the case of jellyfish samples it was not convenient to measure length, and the thermal behaviour was determined by observations of stress relaxation in the slightly extended specimen. One end of the specimen was held in a fixed clamp while the other was connected to a very stiff force transducer. Stress variation was recorded on a chart recorder. Ultimately, both methods detect molecular relaxation processes whether they be first or second order thermal transitions. The stress relaxation method, however, is somewhat more versatile as it is independent of sample dimensions.

Before beginning an experiment the samples were conditioned at the lowest experimental temperature for at least 16 h, or until, in the case of stress relaxation experiments, equilibrium was attained. Two heating rates were used: 0.1 or 0.5°C min⁻¹, but no difference could be detected between results obtained with either.

Table 1 Mean values for the three thermal transitions defined in Fig. 1 for the collagen of two earthworms and a jellyfish

Animal	No. of experiments	T_A	T_B	T_S	Preferred temperature range
<i>A. caliginosa</i>	10	8	23	35	10–23 (ref. 10)
<i>E. foetida</i>	6	12	23	35	16–23 (ref. 10)
<i>A. coerulea</i>	7	17	27	50	17–25 (ref. 3)

The range of preferred temperatures for the two earthworms reported by Grant¹⁰ are listed. In the case of the jellyfish, the range has been listed as that over which the pulsation rate of the bell is uniform and linear³, but is also close to the seawater temperature limits which the animal frequents.

Both experiments gave rise to a characteristic curve (Fig. 1). There is always a linear region in which there is little change in length or force with temperature. The first transition occurs at A, then a less marked transition at B, and finally the sample shrinks. The temperatures at which the three transitions take place are denoted by T_A , T_B and T_S . At T_S , the familiar shrinkage temperature, the length decreases for the freely suspended sample and force increases in the stress relaxation experiment, because the sample is constrained. As long as the temperature is not allowed to exceed T_B by more than 2–3°C the sample may be cooled to below T_A and the cycle repeated. In other words the transitions are reversible. In Figs 2 and 3 the dotted lines are drawn to show more clearly the transition at A and B. The mean values for the transitions in all experiments, including another species of earthworm *Eisenia foetida* are given in Table 1.

A full description and interpretation of these transitions will be given elsewhere. Here we are interested only in the biological significance of the transitions, especially those occurring at A and B. We have already said that T_S marks the region of the well known thermal shrinkage phenomenon, which has been shown to be a manifestation of the melting of crystalline collagen^{4,5}.

The mean temperature of the transition at B of the collagen of *A. caliginosa*,^{1,6} and *A. coerulea*³ agrees with the temperature at which the molecular collagen melts in dilute solution (that is, T_D , the mid-point of the transition as determined by optical rotation or viscometry), or what we have shown to be equivalent—the temperature at which these tissues shrink when heated in HCl solution at pH 1 (ref. 7). Determination of T_D for the collagen of *E. foetida* in HCl gave 22°C, which again is close to T_B . A number of other earthworms^{1,6} have a T_D value of

22°C, and Maser and Rice⁸ and Josse and Harrington⁹ using optical rotation report 22°C for another earthworm *Lumbricus terrestris*. So, we think it justifiable to equate the tissue transition T_B with T_D , the molecular transition.

Before commenting on the transition at A we need to consider the following. The molecular melting temperature, T_D , of the collagen of a wide range of animals agrees with the upper limit of their preferred thermal range, if they are poikilothermic, or with their normal body temperature if they are homeothermic^{1–3}. Now, in view of the preceding paragraph, when dealing with tissues, we can say that T_B correlates in the same way. When we found the transition at A, we wondered if it had any relation to the lower limit of the preferendum. This turned out to be the case on examining the literature. First, our own data³ for the jellyfish *A. coerulea* showed that, over the range 17°–26°C the pulsation rate of the bell of a live animal was uniform and linear with temperature, at 15°C the jellyfish had become sluggish, while above 28°C the pulsation rate dropped very rapidly. Furthermore, the mean limits of surface water temperature along the New South Wales coast where the animal was taken, are 17°–23°C (ref. 3).

Although we originally linked the upper value of 26°C (as determined by the pulsation behaviour of the bell) with the value of the melting temperature of its collagen, we did not look for evidence of a structural transition near the lower limit of 17°C. These data have been incorporated into Fig. 3, and an examination of the figure shows that thermal transitions A and B (curve 1) are very close to the lower and upper limits of the normal pulsation rates of the jellyfish respectively.

Fig. 3 A stress relaxation-temperature curve for jellyfish connective tissue in 0.9% NaCl, together with data (●) showing the pulsation rate of the bell plotted against temperature for a live jellyfish in seawater³. The species was *A. coerulea*.

(curve 2), and both points correspond well with the limits of its range of preferred temperatures³. Second, in the case of the earthworm it has been reported by Grant¹⁰, that *A. caliginosa* and *E. foetida* have thermal preference ranges of 10°–23°C and 16°–23°C respectively. The upper limits agree very well with T_B in Table 1, and the lower limits are close to T_A for each species.

We suggest that transition temperature T_A marks the lower limit of the animal's range of preferred temperatures just as T_B (or, T_D in dilute solution studies on molecular collagen) marks the upper limit. Further, it seems that transition A represents the beginning of a disorganisation of molecular collagen, but that complete melting of the molecule in dilute solution will not take place until a temperature greater than T_B is reached. Whether the properties of collagen determine the range of preferred temperatures or vice versa, is an open question.

When we compare dilute solution studies with tissue studies only T_D and T_B are coincident. There is no evidence in the work of either Maser and Rice⁸ or of Josse and Harrington⁹ of a transition at a temperature corresponding to T_A . This may be because they used a different species of earthworm, or because the use of native tissue preserves non-collagenous components

which give rise to the transition at A, or possibly, there are other collagens with lower thermal stabilities, which have been destroyed by the usual solubilisation procedure

Reduced maximal levels of derepression of the isoleucine-valine and leucine enzymes in *hisT* mutants of *Salmonella typhimurium*

STRAINS of *Salmonella typhimurium* with a mutation in the *hisT* locus, produce an enzyme that cannot convert two uridine residues to pseudouridine in the anti-codon region of tRNA^{His} (refs 1 and 2). This mutation allows constitutive synthesis of the histidine biosynthetic enzymes^{1,3}. Recently, *hisT* mutants were found to have changes in tRNA^{Leu} (refs 1, 4 and 5), in tRNA^{Ile} (ref 6), and to be partially derepressed for the isoleucine-valine biosynthetic enzymes^{5,6}. This suggests strongly that tRNA is part of the repression machinery for these enzymes. We report here that *hisT* strains are greatly limited in their ability to derepress the isoleucine-valine and leucine enzymes during leucine starvation. Thus, the *hisT* mutation alters regulation of these enzymes in two ways, it seems to cause a marked reduction in their maximal level as well as leading to a partial loss of repressibility.

A leucine-requiring strain of *S. typhimurium* containing the *hisT1504* lesion was constructed by transduction with phage P22. When the strain was grown in the presence of excess branched-chain amino acids, the level of the isoleucine valine and leucine enzymes was essentially the same as that found for the prototrophic *hisT1504* parent strain (Table 1). During leucine starvation these enzymes were increased two- to three-fold in the strain containing both *hisT* and *leu* mutations, while the isogenic strain without the *hisT* mutation was derepressed 14- to 116-fold when grown under the same conditions (Table 1). This effect seems specific for the isoleucine-valine and leucine enzymes since the levels of two unrelated enzymes, hexokinase and acetylornithinase, are equivalent in both strains during leucine restriction (M F unpublished).

Fig. 1 *In vivo* levels of charged tRNA^{Leu} in the *hisT* strain grown on limiting leucine. The cells were grown in minimal medium with L-isoleucine (50 µg ml⁻¹), L-valine (100 µg ml⁻¹) and L-leucine (9 µg ml⁻¹). The tRNA was isolated as described previously⁵ except that after phenol extraction and centrifugation, the aqueous phase was layered on to a DEAE-cellulose column equilibrated with 0.3 M LiCl in 0.1 M sodium acetate buffer, pH 5.0. The column was then washed with several bed volumes of this buffer. The tRNA was eluted with 1.0 M LiCl and precipitated with 2.5 volumes of ice-cold ethanol. The isolated tRNA was divided into two portions, one was kept as control and the second sample was oxidised with sodium periodate as described previously⁵. The control and periodated samples were charged with ³H-leucine and ¹⁴C-leucine respectively and mixed and cochromatographed on an RPC-5 reversed-phase column as described previously⁵. The altered mobility of the last two isoacceptor species from the periodated sample is an artefact of the periodate oxidation procedure⁵ (A A R and M F, unpublished). ● — ●, ³H unperiodated, ● — ●, ¹⁴C periodated.

To investigate this further, both strains were grown with various amounts of leucine. The levels of the isoleucine-valine and leucine enzymes in the strain with the *hisT* mutation did not change more than threefold for the entire range of leucine concentrations (Table 2). There was a strong inverse relationship between the amount of leucine and the enzyme levels found in the isogenic strain. Growth of these strains in a chemostat with a limiting supply of leucine produced similar results (Table 2). Under all conditions tested the *hisT* mutation seems to have curtailed the range of derepression during leucine limitation as well as reducing the maximal level of the isoleucine-valine and leucine enzymes that can be made under these conditions.

The limited ability of strains with a *hisT* mutation to derepress is not common to all strains that show partial constitutive

Table 1 Effect of the *hisT* mutation on derepression of the isoleucine-valine and leucine enzymes and levels of charged tRNA

Mutation	Growth conditions	Threonine deaminase	Specific activity		tRNA charged <i>in vivo</i> (%)	
			Acetohydroxy acid synthetase	β-IPMD	Leucine	Valine
<i>leu124</i>	Excess leucine	8.2	0.7	1.7	82	90
<i>leu124</i>	Limiting leucine	107.6	82.3	91.2	27	87
<i>hisT1504 leu124</i>	Excess leucine	21.2	7.6	12.4	91	88
<i>hisT1504 leu124</i>	Limiting leucine	33.6	18.9	20.3	18	92

All bacterial strains were derived from *S. typhimurium* LT-2. The strain containing the *hisT1504* mutations was constructed by P22 transduction⁷. The *hisT* allele was transduced into a strain containing the mutations *aroD38 leu124*, selecting for Aro⁺ recombinants. The *hisT* lesion was identified by colony morphology⁸, growth rate⁹, tRNA^{Leu} profile^{1,5} and enzyme levels^{5,6}. The minimal medium and growth conditions were as described previously⁵. The minimal medium was supplemented with L-isoleucine (50 µg ml⁻¹), L-valine (100 µg ml⁻¹) and excess L-leucine (50 µg ml⁻¹) or limiting L-leucine (7.5 µg ml⁻¹). Enzyme specific activity is expressed as µmol of product per mg of protein per hour. The preparation of the crude cell extracts and the measurement of enzyme activity and protein was as described previously⁵. The leucine enzyme measured in this study was β-isopropylmalate dehydrogenase (β-IPMD). Isolation and periodate oxidation and the percentage of tRNA that existed in the charged form *in vivo* were as described previously⁵.

Table 2 Effect of the *hisT* mutation on derepression during growth limitation on various concentrations of leucine

Mutation*	L-Leucine ($\mu\text{g ml}^{-1}$)	Specific activity		β -IPMD
		Threonine deaminase	Acetohydroxy acid synthetase	
<i>leu124</i>	7.5 chemostat†	123.2	82.5	61.6
<i>leu124</i>	7.5	101.1	61.2	97.4
<i>leu124</i>	12.5	59.9	45.0	76.3
<i>leu124</i>	15	53.3	19.4	47.0
<i>leu124</i>	17.5	42.3	16.0	32.8
<i>leu124</i>	20	27.7	8.3	18.1
<i>leu124</i>	50	5.6	1.0	1.4
<i>hisTleu124</i>	7.5 chemostat	51.0	25.0	28.0
<i>hisTleu124</i>	7.5	41.0	26.1	23.0
<i>hisTleu124</i>	12.5	30.0	10.8	14.8
<i>hisTleu124</i>	15	28.5	10.8	13.2
<i>hisTleu124</i>	17.5	29.6	10.6	12.3
<i>hisTleu124</i>	20	27.4	7.9	12.0
<i>f1rB1leu124</i>	7.5	138.0	118.6	130.0
<i>f1rB1leu124</i>	50	63.8	77.0	55.2

*The strain containing the *f1rB1leu124* mutations was constructed by transducing the *leu124* mutation into a strain containing the mutations *ara1r123*, selecting for *Ara*⁺ recombinants. *f1rB* strains are resistant to the leucine analogue 5',5'-trifluoroleucine and are constitutive for enzymes forming branched-chain amino acids. The biochemical basis for this phenotype is unknown¹⁰.

†In experiments with a chemostat the minimal medium was supplemented with L-isoleucine (50 $\mu\text{g ml}^{-1}$), L-valine (100 $\mu\text{g ml}^{-1}$) and L-leucine (7.5 $\mu\text{g ml}^{-1}$). Enzymes were measured after four doublings. All other experiments involved Erlenmeyer flasks for measurements of growth and enzyme levels. The minimal medium contained L-isoleucine, L-valine and L-leucine, as indicated. In all experiments the doubling time of the *hisT* mutant was 30–35% less than the isogenic strain. This reduced growth rate is about the same as reported for *hisT* strains prototrophic for leucine, grown in minimal medium¹. For all other conditions and explanations see Table 1.

synthesis of the enzymes. A strain with a *f1rB1* mutation is highly rederepressed for the isoleucine–valine and leucine enzymes due to a mutation other than *hisT* (ref. 10). We transduced the same *leu* mutation into this strain as we had for the *hisT1504* mutant. Derepression of the isoleucine–valine and leucine enzymes during leucine starvation was greater in this mutant than in the isogenic leucine-requiring strain and three to five times greater than for the *hisT* leucine auxotroph (Table 2).

A direct correlation has been found between decreased levels of charged tRNA^{Leu} and derepression of the isoleucine–valine and leucine enzymes¹¹. The difference in derepression found in the strain with the *hisT* mutation might therefore be due to variations in tRNA^{Leu} acylation during leucine starvation. This does not seem to be the case since bulk tRNA^{Leu} was about equally deacylated in both strains when they were starved for leucine (Table 1). In addition, the *in vivo* charging of the individual species of tRNA^{Leu} was examined by the reversed-phase chromatography system (RPC-5) of Kelmers and Heatherly¹². All components of leucine-acceptor activity were highly deacylated when the strain with the *hisT* lesion was grown on limiting amounts of leucine (Fig. 1).

Previous work has established that tRNA^{Leu} is altered in *hisT* mutants and that these strains are partially derepressed for the isoleucine–valine and leucine enzymes^{1,5,6}. In addition, our results suggest that the *hisT* mutation alters further the repression mechanism in these pathways by reducing their maximal expression during leucine limitation. These data offer additional evidence for the involvement of tRNA^{Leu} in repression of the isoleucine–valine and leucine enzymes. The dual effect of the *hisT* mutation on the regulation of these enzymes suggests that the lack of pseudouridine in the anticodon region of tRNA^{Leu} introduces a conformational change in the tRNA which affects both minimal and enzyme levels. Thus, the conformational change which may normally occur in tRNA^{Leu} during aminoacylation to cause repression may be defective in tRNA^{Leu} from *hisT* mutants. In addition, this conformation may elicit partial repression even if the tRNA is deacylated. Alternatively, a species of tRNA^{Leu} may have a positive role in regulation. The alteration of such a species in *hisT* mutants could prevent

the full expression of the isoleucine–valine and leucine enzymes. Because of the pleiotropic nature of the *hisT* mutation^{1,2}, it is possible that another altered tRNA rather than, or in addition to tRNA^{Leu} is responsible for these changes in repression. Cortese *et al.*⁶ reported a possible alteration in a minor species of tRNA^{His} in *hisT* mutants. Changes in tRNA^{His} do not, however, seem to alter the regulation in these systems since the form of acetohydroxy acid synthetase that is not subject to feedback inhibition by valine is not disproportionately elevated in *hisT* strains (unpublished observations of M. F.). It has been shown that due to an alteration in the isoleucine 'repression signal' the resistant but not the valine-sensitive form of acetohydroxy acid synthetase is derepressed^{13,14}. It is also conceivable that the encoded product of the *hisT* gene could be involved in regulation of the isoleucine–valine and leucine enzymes. Utilisation of *hisT* mutants in an *in vitro* protein synthesising system will aid the choice from among these possibilities.

Chromosome-21-dosage effect on inducibility of anti-viral gene(s)

UNLIKE the bacterial situation little is known about gene regulation in mammalian cells. Inducible systems are being used to study regulatory gene functions in normal and abnormal mammalian cells^{1–3}, and have shown for example, that inhibitors of macromolecular synthesis enhance rather than inhibit the expression of an inducible enzyme. Actinomycin D enhances the induction of tyrosine aminotransferase (TAT) by steroid hormones in hepatoma cells⁴. Commonly referred to as superinduction, this effect has led to the hypothesis that a regulatory gene(s) modulates the expression of the structural TAT gene⁴. Of course, alternative explanations have been offered for the superinducing effect of actinomycin D (refs 5 and 6). Similarly, the induction of interferon by viruses and poly(I).poly(C) and the induction of the anti-viral state (AVS) by interferon have been used to probe regulatory mechanisms in normal mammalian cells^{7–13}. It has been demonstrated that with judicious use of metabolic inhibitors the amount of interferon and the level of AVS induced can be enhanced 100–1,000 times and 10–100 times respectively, over that obtained in cultures exposed to inducer alone. This suggested that one or more regulatory gene(s) modulate the expression of the structural gene for interferon and AVS^{7–19}.

Fig. 1 Induction of the AVS in human skin fibroblasts: monosomic (cell line 198 halved symbols), disomic (cell line 141 closed symbols), and trisomic (cell line 258, open symbols) for chromosome 21 by human interferon. Three sets of experiments were performed for each cell line described.

I have used a new approach to assess the presence of a regulatory gene function which modulates the expression of the structural gene for AVS. I found evidence to suggest that the regulation of the anti-viral genes in human cells is controlled by regulatory gene element(s) located on a separate chromosome.

AVS was induced in human fibroblast cultures trisomic (T-21) disomic (D-21) and monosomic (M-21) for chromosome 21, trisomic for chromosome 18 (T-18), monosomic for chromosome 5 (M-5) and carrying a partial deletion of chromosome 4 (M-4) by exposing them to various concentrations of human interferon. The level of AVS induced was estimated by assessing the amount of interferon required to inhibit viral RNA synthesis by 50%. Figure 1 and Table 1 show that M-21 fibroblasts were less sensitive to the anti-viral action of interferon than normal diploid fibroblasts, which were in turn less sensitive than T-21 fibroblasts. The concentration of interferon required to induce AVS in M-4, M-5 and T-18 fibroblasts falls within the same range of concentrations required to induce AVS in normal diploid fibroblasts, suggesting that the effect of

Fig. 2 Gene dosage effect of chromosome 21 on the induction of the AVS in human fibroblasts monosomic, disomic and trisomic for chromosome 21. Each point represents the mean reciprocal concentration of human interferon (HuIF) required to induce the AVS in the fibroblasts. The mean concentration of interferon is derived from the figures given in Table 1.

Human fibroblast cultures established from skin biopsies were provided by the Mammalian Genetic Mutant Cell Repository, Camden, New Jersey, the Repository for Mutant Human Cell strains, Montreal and by Drs J. Mahoney and K. Halloran of Yale University. Three human fibroblast cultures trisomic for chromosome 21 (T-21) designated GM-258, DS-GG1 and DS-GG2, three human cultures monosomic for chromosome 21 (M-21) designated GM-137, GM-230 and 198, three normal diploid human skin fibroblasts, disomic for chromosome 21 (D-21) designated GM-37, GM-181 and 141, and two human fibroblast cultures, one known to carry a partially deleted chromosome 4 and the other known to have one less chromosome 5 designated GM-72 and GM-71 respectively were used. A trisomic 18 human fibroblast (T-18) derived from a previous study²⁷ was also used as one of the controls for the trisomic 21 cultures. The monosomic 21 lines used were verified by the Mammalian Genetic Mutant Cell Repository to contain 45 human chromosomes and to lack one chromosome 21. No translocation was evident. The amount of vesicular stomatitis virus replication was assayed by Skehan's method²⁸ except that (a) the cultures were exposed to actinomycin D ($4 \mu\text{g ml}^{-1}$) for 1 h before the viral challenge and (b) the cultures were incubated with the virus for 8 h instead of 14–17 h at 37°C . This modification of the procedure was introduced to reduce variability in the estimation of viral RNA synthesis. The results listed for the same cell type were derived from the fibroblasts at early cell passages. The interferon used in this study was derived from a large batch of human interferon that was contributed by Dr J. Valenta of Smith, Kline and French Pharmaceutical. This was purified through two cycles of gel filtration on Sephadex G-75 columns. The purified interferon had a specific activity of $\sim 1 \times 10^5 \text{ U mg}^{-1}$ protein. The unit of interferon described here is based on the internal standard of Smith, Kline and French interferon.

chromosome 21 on AVS is not a generalised effect resulting from the loss or gain of a human chromosome.

Figure 1 and Table 1 also show that the inducibility of the AVS in human cells increases nonlinearly for each increment in the number of human chromosome 21 present. To analyse this effect, the mean concentration of human interferon required to induce the AVS in fibroblasts containing one, two or three chromosome 21 (Table 1) was plotted logarithmically against the number of chromosome 21. A straight line was obtained which can be expressed by the equation

$$\log Y = 0.61X$$

where Y denotes the inducibility of AVS and X the number of chromosome 21 (Fig. 2). Thus, the inducibility of AVS increases logarithmically as the number of chromosome 21 increases linearly. Extrapolation of the curve to the origin suggests that a cell cannot be induced for AVS if chromosome 21 is absent. This confirms the assignment of the AVS gene(s) to chromosome 21 (ref. 18).

Before attempting to interpret the significance of this logarithmic gene dosage effect, it is useful to consider events that might contribute to the establishment of the AVS. They are (1) the uptake of interferon by its receptor sites, (2) the depression of the structural gene(s) which code(s) for AVS by an inducer, presumably interferon, (3) the transformation of cells into an AVS through production of an anti-viral protein, and (4) the modulation of the level of the AVS by regulatory gene element(s).

The existence of interferon receptor sites has not been substantiated. The existence of the structural gene(s) described in step (2) is based on genetic analysis of somatic cell hybrids derived from hamster \times mouse, monkey \times mouse

and human×mouse¹⁷⁻²⁰ This has led to the assignment of the gene(s) which codes for AVS and the cytoplasmic form of superoxide dismutase to chromosome 21 in man¹⁸

The mechanisms of transformation of a cell to an AVS in step (3) is unclear, though it is presumed to be mediated by a protein²¹ which inhibits the translation of exogenous mRNA²²⁻²⁶ Conceivably the chromosome-21-directed AVS gene(s) produces this inhibitor substance I have already discussed the existence of the regulatory gene function in step (4)

Accordingly, any increase in the number of chromosome 21, should be followed by a linear and proportional increase in the amount of chromosome-21-directed gene products Instead my data show a logarithmic increase, showing that other complex mechanisms, presumably of a regulatory nature are involved One such mechanism is that (1) the regulatory gene element(s) postulated by Chany *et al*¹⁰ or (2) the repressor substances which normally maintain the anti-viral gene(s) in a non-constitutive state, is not located on chromosome 21 The effect of an increase in chromosome 21 would be an imbalance in the ratio of the AVS gene(s) and its regulator gene element(s) which is postulated to be located on a chromosome other than 21 This imbalance could mitigate the normal role of the regulator gene(s) in controlling the levels of AVS directed by the AVS gene(s)

The logarithmic increase in the amount of chromosome-21-directed product as the number of chromosome 21 increases linearly indicates that cellular induction of AVS can be mediated through interchromosomal gene interactions This can be tested, for example, using an interferon selective system on a population of aneuploid human cells to select for cells expressing high and low levels of AVS The levels of AVS in turn are determined by chromosome 21 dosage and dosage of the chromosome(s) other than chromosome 21 carrying the regulator gene element(s) for AVS In any event, it is possible that cellular regulation by interchromosomal gene interaction is responsible for human disorders associated with the loss or gain of a single human chromosome

I thank Dr T Makinodan for helpful discussions and the Damon Runyan-Walter Winchell Fund for a grant

Multiple conformations of ribosomal precursor RNA

We wish to propose an explanation for the heterogeneity shown¹ by ribosomal precursor RNAs on gel electrophoresis The clearest demonstration of this phenomenon is shown in Fig 1 ³²P-labelled RNA was eluted from single gel slices taken across the peak, and rerun in the presence of ³H-labelled marker The ³²P-RNA samples run in their original positions and not coincidentally with the marker, that is, the width of the peak does not result from diffusion alone

A heterogeneity of the 45S precursor of L cells has also

Fig 1 The heterogeneity effect The lower histogram represents ³²P-radioactivity in 0.5 mm slices from the 40S peak of *Xenopus* RNA run on a 2.4% polyacrylamide gel RNA was eluted from individual gel slices by the method described¹ Each sample was mixed with 40S RNA labelled with ³H-uridine and rerun on a second 2.4% gel (upper histograms a-d) These gels were sliced to 0.5 mm and the slices were counted in scintillator ---, ³H-Radioactivity, —, ³²P-radioactivity The methods used to label the cells, extract the RNA, run, slice and count the gels have been described^{2,3}

been reported, which was demonstrated by the effect of the radioactive pulse length on the gel mobility⁴ Although mobility in polyacrylamide gels depends mainly on molecular weight, it is known that other factors can have an effect⁵ Three possible explanations for the phenomenon may be proposed, although they are not necessarily mutually exclusive (1) The original RNA peak is actually a mixture of components differing in length, perhaps because of processing reactions, (2) heterogeneity in primary sequence, because of divergence between the multiple ribosomal gene copies, is sufficient to cause a heterogeneity in gel mobility, and (3) the heterogeneity is caused by differences in secondary structure between otherwise identical molecules

Fig. 2 Abolition of heterogeneity by formamide treatment of *Xenopus* 40S RNA. ^{32}P -labelled RNA from the indicated slices was mixed in E buffer³ with total cell RNA pulse labelled with ^3H -uridine. The mixtures were divided, half being run as controls (a and c) and the other half (b and d) being treated before running with 70% formamide at 37° C for 5 min. The formamide was deionised by passage through mixed Amberlites IR 120/IRA-400. All glassware and solutions were sterilised with a dilute solution of diethyl pyrocarbonate. -----, ^3H -Radioactivity, ———, ^{32}P -radioactivity.

Figures 2 and 3 show the effect of partial denaturation of the eluted RNA fraction (plus marker) using heat treatment or formamide. Figure 2 shows the 40S *Xenopus* precursor^{3,6} and Fig 3 the 42S precursor from yeast^{7,8}, in our case *Schizosaccharomyces pombe*. In both experiments the heterogeneity has been abolished by the treatment, thus ruling out the first of the possible explanations. In addition,

Fig. 3 Abolition of heterogeneity by heat treatment of yeast 42S RNA. The experimental design was the same as that of Fig 2 except that the treatment consisted of heating to 60° C for 5 min. -----, ^3H -Radioactivity, ———, ^{32}P -radioactivity.

the 40S RNA has a unique 5' terminal nucleotide⁹. The second explanation could still be correct insofar as any primary sequence divergence might manifest itself as secondary structure differences. If it could be shown that the RNA reanneals during the period for which the gel is run, usually 4 h, this would be unlikely. It should be stressed that the formamide treatment lasts for 5 min only and the gels are normal ones, run in an aqueous medium rather than the denaturing formamide medium described by Staynoff *et al*¹⁰.

The total RNA preparation was treated with formamide and the RNA from single slices of the precursor peak rerun with marker. The heterogeneity is evident from Fig 4, indicating that the RNA does reanneal within the gel. We would not, therefore, expect the experimental procedure of Figs 2 and 3 to remove heterogeneity caused by the effect of primary structure divergence on secondary structure. Furthermore, since heterogeneity can reappear after treatment of the total RNA, it would seem that the relevant secondary structure differences are characteristic of the molecules themselves rather than of other influences *in vivo*. For example, ribosomal proteins can affect the conformation adopted by ribosomal RNA¹¹.

The most likely interpretation of these experiments is that several secondary structure configurations are accessible to the molecules but that they do not readily interconvert once formed. Unless there is something peculiar

Fig 4 Retention of heterogeneity after formamide treatment of the ^{32}P -labelled total cell RNA before running it on the first gel. -----, ^3H -Radioactivity, ———, ^{32}P -radioactivity.

about ribosomal precursor RNAs this suggests that other high molecular weight RNAs should show the same effect, and in fact we have found a small heterogeneity *Xenopus* 28S RNA and yeast 18S RNA which is not found after partial denaturation.

An RNA molecule is usually presumed to have a definite secondary structure which is the most stable arrangement of its primary sequence in antiparallel A-U and C-G base paired loops^{12,13}. The most stable arrangement may not be the same in different chemical environments, for

example, denatured forms of transfer and 5S RNA are known which are produced by the action of urea and EDTA^{14,15}, and in the case of 5S RNA the two forms are known to have different arrangements of the base paired regions¹⁶.

What our experiments suggest is that a collection of identical molecules placed in the same environment can spontaneously attain a range of different secondary structures. Structures may be regarded as different when the activation energy for interconversion is too high for rapid equilibration to occur (by comparison the activation energy for 5S renaturation has been found to be about 65 kcal/mol¹⁷). We would expect this property to be more evident for the high molecular weight RNAs because the greater length of the sequence should allow more base pairing arrangements, and indeed the low molecular weight RNAs isolated with modern techniques seem to be homogeneous in their three-dimensional structure, as evidenced, for example, by the crystallisation of tRNA^{18,19}.

Crystal structure of proflavine, a DNA binding agent

THE subject of DNA-small molecule binding has received much attention in recent years. Particular emphasis has been placed on aminoacridine binding¹, and many studies have employed proflavine (Fig 1) as perhaps the classical interacting agent of these series of drugs. The DNA-binding properties of proflavine cause it to act as a frameshift mutagen, and this ability has been extensively utilised in molecular genetics².

Proflavine has been shown to bind to DNA in two ways^{1,3}. First a strong interaction at low drug concentrations, involving intercalation of the planar drug molecule between successive base pairs⁴, and second a weaker process at higher drug levels primarily concerned with interactions with the phosphates external to the DNA double helix, although the precise stereochemical details of both the binding modes are not clear. It has been suggested, in a modification to the original intercalation model, that strong binding also involves ring

nitrogen-phosphate interactions⁵. As part of our studies directed to understanding drug-DNA binding, we have determined by single-crystal X-ray analysis the structure of proflavine itself, as the biologically active hemi-sulphate.

Proflavine hemi-sulphate crystallises from aqueous solution as well-formed, deep-red elongated prisms, belonging to the monoclinic space group $P2_1/c$. The cell dimensions are $a=12\ 703(1)$, $b=19\ 940(2)$, $c=21\ 487(2)$ Å, and $\beta=92\ 24(1)^\circ$. This surprisingly large unit cell, together with measurements of crystal density, suggested that there were several proflavine

Fig. 1 Proflavine

molecules in the crystallographic asymmetric unit, and this has been confirmed by our structure analysis. A total of 5,600 independent reflection intensities were measured on an automatic four-circle diffractometer.

The structure was solved by a combination of direct methods⁶ and reciprocal-space search procedures⁷, and refined by least-squares methods to a final discrepancy index of 0.0736. (The full details of the structure solution, as well as other crystallographic discussion, will be published elsewhere.) All the hydrogen atoms were located, except those attached to water molecules. As suggested by Albert⁸, the cationic charge of the proflavine rings has been found to reside exclusively on the central nitrogen atom, as evidenced by the location of a hydrogen atom attached to this atom, and coplanar with the ring. Our analysis has revealed that the asymmetric unit consists of four proflavine molecules, together with two sulphate ions and seven water molecules, a total of 81 independent non-hydrogen atoms. These four proflavine molecules are not related by any local symmetry elements.

The crystal structure has a number of features of interest. As might be expected, the lattice is held together by a complex network of hydrogen-bonding and electrostatic interactions. Figure 2 shows one unit of four proflavines, and illustrates their peculiar clustering around the sulphate ions, with one of

Fig. 2 a and b two views of the four proflavine molecules and two sulphate ions in the crystallographic asymmetric unit. Dashed lines represent intramolecular interactions between these, other interactions with neighbouring molecules, and water molecules, have been omitted for reasons of clarity. The right-hand view represents a 90° rotation about the vertical axis, with respect to the left-hand one.

the latter being particularly intimately involved. Three of the four proflavines are strongly hydrogen—(and electrostatically) bonded from their central ring nitrogen atoms, to this sulphate. The fourth molecule is attached by an amino nitrogen, to both sulphate ions. The charged nitrogen to sulphate-oxygen interactions are strong ones, with nitrogen-oxygen distances being between 2.70 and 2.87 Å. Thus, the overall arrangement is dominated by tight hemispherical clusters around the central sulphate ion. The water molecules serve mainly to act as a means of hydrogen-bonding the units together, with involvement of the proflavine amino-nitrogen atoms, as well as the charged sulphate ions. The overall hydrogen-bonding scheme has almost, though not quite, satisfied fully the hydrogen-bonding capability of the various groupings.

A distinctive feature of the crystal structure is the unimportance of ring system stacking. Of the four molecules in the asymmetric unit, only two overlap to any appreciable extent, although all four have their long axis pointing in roughly the same direction. There is no stacking between adjacent molecules in symmetry-related units. This situation contrasts notably that observed in the rather simpler proflavine dichloride crystal structure⁹, as well as in many other aminoacridines¹⁰.

Fig 3 Skew stacking of two proflavine cations

These all have straightforward crystal structures with considerable parallel molecular overlap. The unusual skew stacking observed here is shown in Fig 3. The two ring systems are not related by any symmetry elements, crystallographic or non-crystallographic. One molecule is twisted relative to the other by 150°, and the charged nitrogens are on opposite sides. The two molecules are almost planar, with a separation of 3.34 Å.

It is interesting to note that proflavine dimerisation in solution has been suggested by a number of workers¹¹ to involve stacking. Whether this is similar to that observed here in the solid state, is of course uncertain. Our studies further suggest that close stacking and aggregation may be relatively unimportant in the external binding of proflavine to the phosphates of a DNA helix, certainly compared to any electrostatic interaction.

This work was supported by a grant from the Cancer Research Campaign. We are grateful to Professor C. J. Carlisle of Birkbeck College, London, for enabling the crystal data to be collected on his diffractometer, and to various colleagues for much useful discussion. T. A. J. thanks the Science Research Council for the award of a postdoctoral Research Fellowship.

Amino acid sequence similarity between cytochrome *f* from a blue-green bacterium and algal chloroplasts

"THE biological gap which separates bacteria and blue-green algae from all other cellular organisms represents one of the largest evolutionary discontinuities in the present day living world".¹ The origin of eukaryotic cells from simpler precursors² is an area of study where speculation is easier than experimental investigation. It seems unlikely that definitive fossil evidence for such early events will ever be obtainable, but molecular methods may be able to give some insight into evolutionary connections between eukaryotes and prokaryotes.

The blue-green algae, unlike other photosynthetic bacteria, carry out oxygenic photosynthesis. The whole photosynthetic apparatus of the blue-green algae bears much more resemblance to that of the chloroplast than it does to that of the other groups of photosynthetic bacteria. The chlorophylls, carotenoids and phycobiliproteins of the blue-green algae are particularly similar to those of the red algae.³ Similar electron transport components are found in both blue-green algae and in chloroplasts.⁴

Photosynthetic eukaryotes contain cytochrome *f* (ref. 5), which has a cytochrome *c*-type spectrum and a high redox potential and functions as one of the links between photosystems 1 and 2. In higher plants this cytochrome *f* is membrane bound and is isolated in an aggregated, although homogeneous form. The cytochrome of corresponding function can be readily isolated from many algae⁶ as a small acidic monomeric protein. Comparable cytochromes have been found in blue-green algae.^{7,8} Other types of photosynthetic bacteria contain a wide variety of cytochromes *c*, but none yet studied is very similar to the algal cytochromes *f* either in physical properties⁹ or in amino acid sequence.^{10,11} The cytochrome *c*-555 from green photosynthetic bacteria^{12,13} is the most similar in properties to the algal cytochromes.

Here we have isolated an *f*-type cytochrome from the blue-green alga, *Spirulina maxima*, and determined the amino sequence. We compare this sequence with the known sequences of algal cytochromes *f*, those of the chrysophyte *Monochrysis lutheri*¹⁴, the euglenoid *Euglena gracilis*¹¹, the phaeophyte *Alaria esculenta* (M. V. Laycock, personal communication), and the rhodophyte *Porphyra tenera* (R. P. A. and R. G. B., unpublished).

The cytochrome *f* was isolated from dried cells of *Spirulina maxima*. The cells were suspended in 0.06 M Tris-HCl, pH 8.0, and broken in a Manton-Gaulin homogeniser. The cytochrome was isolated from the 33-90% saturated ammonium sulphate fraction by chromatography on DEAE-cellulose at pH 8 and by gel filtration through Sephadex G-100. Phycobilins were eliminated with each operation. The cytochrome was finally separated into three fractions by chromatography on DEAE-cellulose (Whatman DE-11), adsorbing the protein from 0.001 M Tris-HCl, pH 8.0, washing the column with 0.01 M buffer, and finally separating and slowly eluting the cytochrome bands with 0.02 M buffer. Each cytochrome was then fractionated with ammonium sulphate and in each case the 60-80%

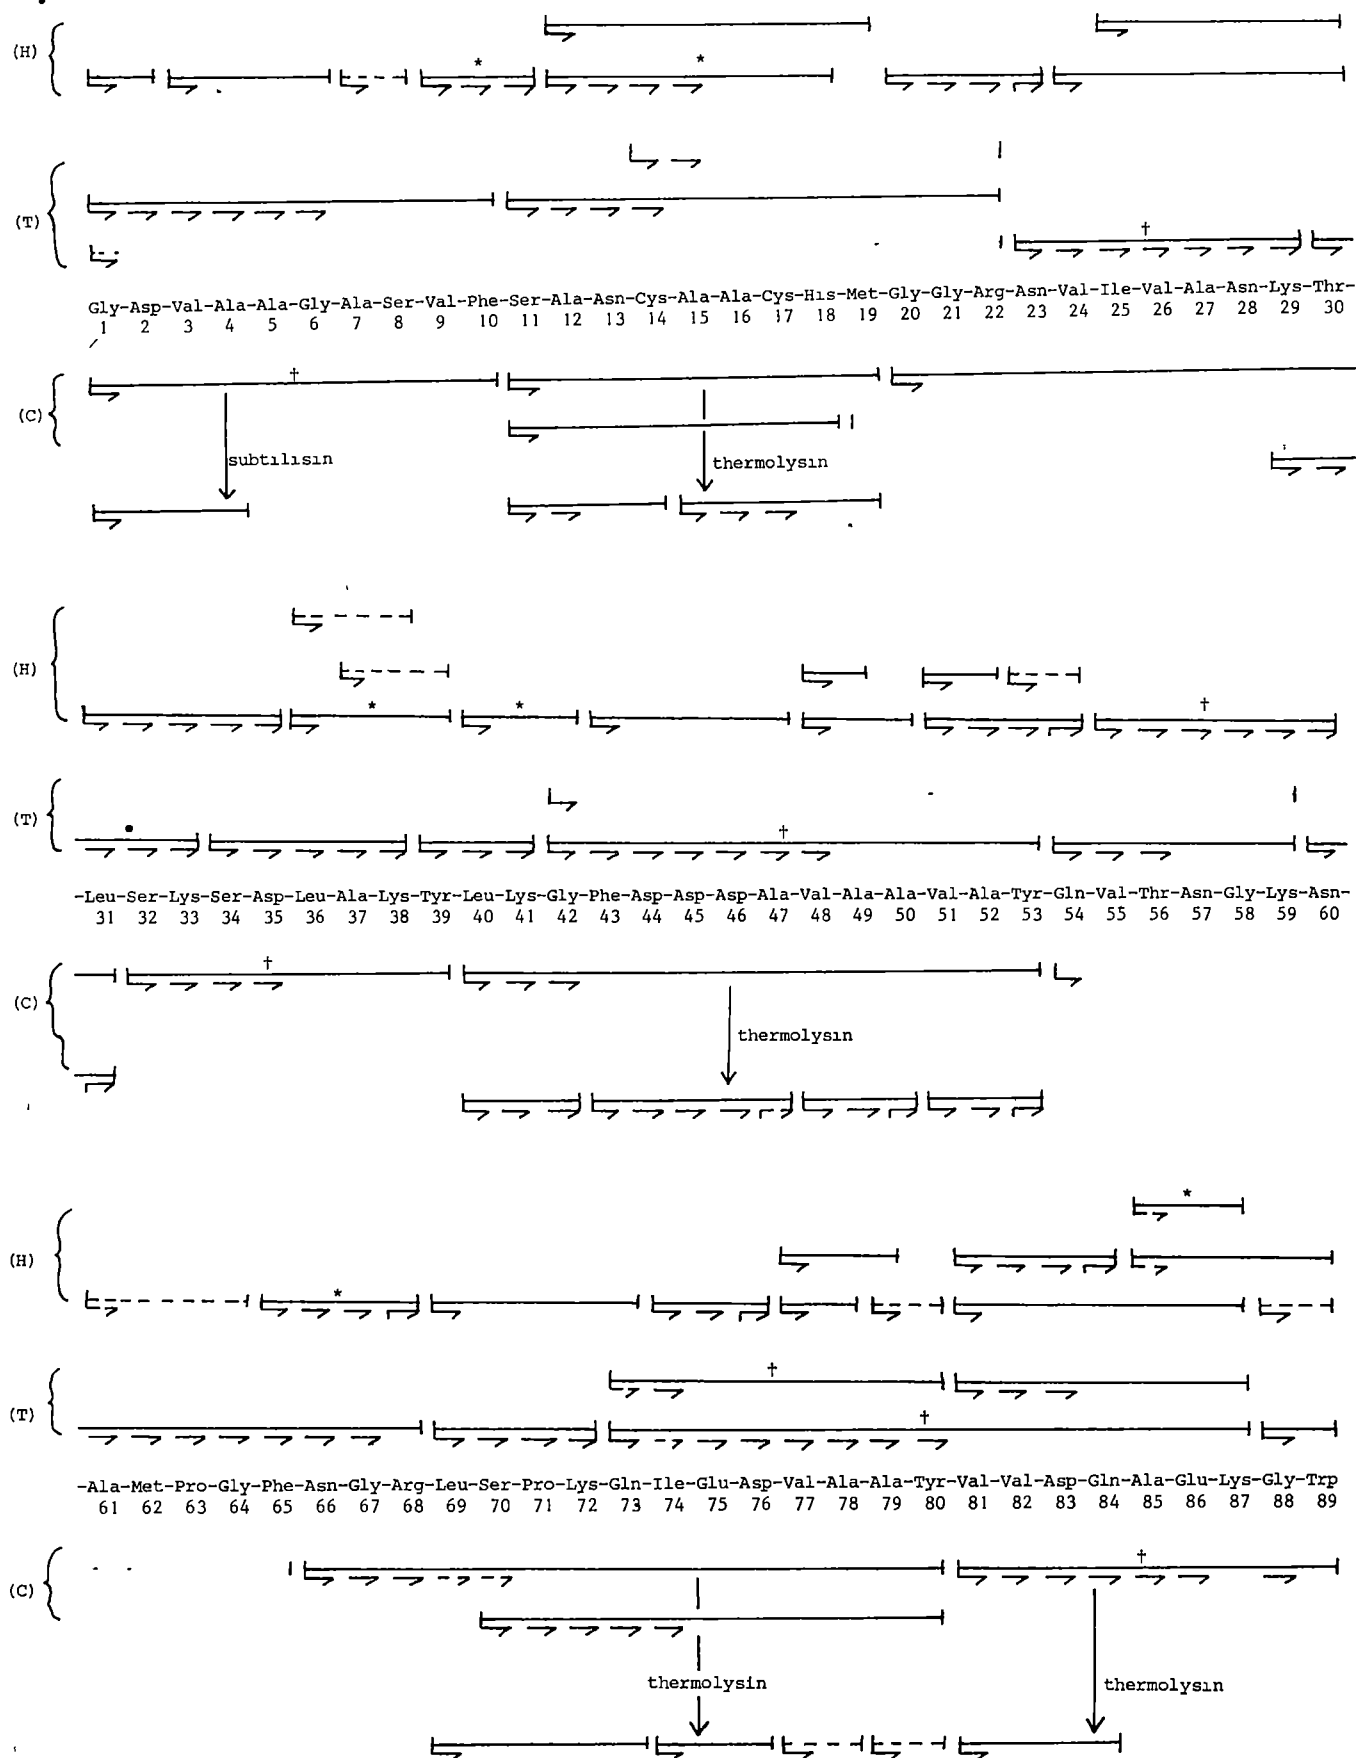

Fig. 1 Amino acid sequence of *Spirulina maxima* cytochrome *f*. Peptides derived by tryptic (T) and thermolysin (H) digestion are shown above the sequence, and by chymotryptic digestion (C) below the sequence. Vertical arrows show peptides produced by further digestion. —, Quantitative amino acid analyses (substandard^{15,16} if marked*), — — —, qualitative analyses, — — — — —, peptides that have definitely been identified as being present in digests but not isolated free from other peptides. — — — — — Indicates end groups and subsequent residues revealed by phenyl isothiocyanate degradation, and identified by the dansyl method (substandard^{15,16} if shown — — — — —), — — — — —, final residues of peptides identified as the free amino acid after the removal of the remainder by phenyl isothiocyanate degradation. † Peptides examined by carboxypeptidase A digestion.

saturated precipitate was collected. During purification, the buffers were kept 0.0001 M in mercaptoethanol or dithiothreitol, which kept the cytochromes in their reduced forms. The final yield of pure protein from 2.8 kg dry cells was about 18 μ mol cytochrome, divided among the three fractions. Portions of each of the three cytochrome fractions which were left standing for four months at 4°C in approximately 70% saturated ammonium sulphate containing 0.02 M Tris-HCl, pH 8.0, formed crystals.

The amino acid sequence was determined by methods similar to those used for some other prokaryotic c-type cytochromes^{15,16}. The haem was removed by treatment with HgCl₂ in 0.1 N HCl/8 M urea, the apoprotein digested with different proteases, and the peptides fractionated by gel filtration, paper electrophoresis and paper chromatography. Peptides were analysed quantitatively for amino acid composition and to assess purity, and sequences determined by the dansyl phenyl isothiocyanate method, by secondary digestion with other proteases and by investigation with carboxypeptidase A. Amide groups were assigned on the basis of electrophoretic mobilities of small peptides, and by the identification of the C-terminal amino acid of peptides by carboxypeptidase release or after the removal of all other amino acids by phenyl isothiocyanate degradation. The peptides isolated and the sequence deduced are shown in Fig. 1.

The proposed sequence contains two -Asn-Gly- sequences (57/58 and 66/67). Such sequences are well known to be particularly susceptible to deamidation¹⁷, especially at alkaline pH. The yields of peptides derived from these regions from the tryptic and chymotryptic digests were very low, and deamidated peptides were also recognised. For these digests, the apoprotein had been separated from urea and HgCl₂ by gel filtration in 0.1 M ammonia solution, as the apoprotein, in common with several other apocytochromes *f*, was insoluble in dilute acid and the peptides had also been eluted from paper with dilute ammonia. For the thermolysin digest, care was taken to avoid alkaline pH, the apoprotein was separated by gel filtration in 50% (v/v) formic acid, the enzymic digestion was carried out at pH 7.5, and peptides containing the susceptible sequences were eluted from paper with M acetic acid. This gave a good yield of the relevant peptides with electrophoretic mobilities that confirmed that asparagine and not aspartic acid was present. They could be quantitatively deamidated

by treatment with 2 M ammonia solution at 37°C for 5 h.

The three ionically distinct forms of the cytochrome *f* were separated by ion exchange chromatography in relative yields (in order of elution from DEAE-cellulose) of 30%, 60% and 10%, respectively. The forms were not distinguished spectrally or by amino acid analysis, and no differences were seen between the thermolysin peptide maps of the three apoproteins. It had been anticipated that the differences might be due to differential deamidation of the susceptible residues 57 and 66, but the peptide maps did not give any support to this hypothesis. The tryptic and chymotryptic peptides (Fig. 1) were isolated from the predominant form, from digests of 2.4 μ mol and 2.0 μ mol apoprotein respectively. The three forms were independently digested with thermolysin, but when the peptide maps showed no differences, the peptides were pooled for purification, resulting in 4.7 μ mol apoprotein for the combined digest. All the thermolysin peptides, even minor peptides isolated in very low yield, were compatible with the sequence shown in Fig. 1, and so there is at present no evidence as to the cause of the ionic differences between the three forms of the cytochrome *f*.

S. maxima cytochrome *f* has been under investigation in other laboratories. Before the present sequence studies began, a sequenator experiment (R. Holton and J. Ramshaw, personal communication) had identified residues 1-7, 9, 10, 12, 13, 15, 16, 23-25 and 27.

The known cytochrome *f* sequences are shown aligned in Fig. 2. It will be seen that there are several regions of good match, particularly around the haem attachment site (residues 14-17) and around methionine-62, the residue that is likely to function as the sixth iron ligand¹¹. In the middle of the sequences there are regions about twenty residues long (positions 34-52) which are very varied, and which are of slightly different lengths in different cytochromes *f*. Pettigrew¹¹ has discussed possible similarities between (*Euglena*) cytochrome *f* and other types of cytochrome *c* from bacteria and eukaryotes.

The sequences have not been compared by elaborate statistical methods, but a crude similarity matrix (Fig. 3) shows that the blue-green algal cytochrome *f* is at least as similar to each of the eukaryotic cytochromes *f* as the latter are to each other, and is considerably closer to the average sequence than is the *Euglena* protein. The distinctiveness of the *Euglena* sequence is in keeping with the many other

Fig. 2 Alignment of the amino acid sequences of cytochromes *f* from blue-green bacteria and eukaryotic algae. a, *Spirulina maxima* (blue-green bacterium), b, *Monochrysis lutheri*¹⁴ (chrysophycean alga), c, *Porphyra tenera* (red alga, R. P. A. and R. G. B., unpublished), d, *Euglena gracilis*¹¹, e, *Alaria esculenta* (brown alga, M. V. Laycock, personal communication). Mml, ϵ -N-methyl lysine. Amides at positions 5, 8 and 13 in sequence, b, have been assigned since original publication¹⁴ (M. V. Laycock, personal communication).

properties which divide the euglenoids from other algae¹⁸. The blue-green algal cytochrome *f* does not seem to be appreciably closer to any of the other bacterial cytochromes *c* than are the eukaryotic cytochromes *f*, but no rigorous searches for similarity have been made.

There seem to be three possible explanations for the close sequence similarity between the algal prokaryote and the algal eukaryote cytochromes *f*. First, the whole genome of the eukaryotic cells are evolutionarily derived from a prokaryote closely related to the blue-green alga, or, second, the eukaryotic chloroplasts are derived from a prokaryote related to the blue-green alga, but the remainder of the eukaryotic genomes are derived from different precursors, or, third, transfer of the cytochrome *f* genes (or of a cluster of genes) has taken place in one direction or other between the blue-green algal line and a eukaryote ancestor. The sequence similarity among the cytochromes *f* is so great that convergence cannot be considered a reasonable possibility.

On the present evidence it is not possible to distinguish between these three hypotheses, and it is not easy to design experiments that would rigorously distinguish between them. Much more sequence evidence will obviously be

needed, both from cytochromes *f* (particularly from other blue-green algae) and from other proteins and nucleic acids. It is important that parts of the blue-green algal genome concerned with functions other than photosynthesis should be compared with the corresponding parts in eukaryotes, for if the second hypothesis (the endosymbiont theory) were correct, the blue-green algal functions might be expected to have atrophied in the chloroplast. By some criteria, such as DNA base composition^{19,20}, the blue-green algae are a very heterogeneous group, but their photosynthetic mechanisms seem to be very much more uniform^{3,21}. This finding is consistent with the second and third hypotheses. Results from bacteria, particularly on the sporadic distributions of homologous proteins^{10,15,16}, suggest that much gene transfer has taken place. If such events (the third hypothesis) have affected a significant proportion of the genomes of a set of organisms over a period of time, then a phylogeny for the set as whole organisms will not exist. Sequence studies would then not be able to provide results from which a tree relating the major groups of organisms² could be deduced, but may be able to show that such trees are a meaningless oversimplification of what must actually have happened.

Very recently N-terminal sequence homology has been reported between the C-phycoerythrins of blue-green bacteria and the corresponding proteins of *Cyanidium caldarium*²², a eukaryotic alga of anomalous properties.

This work was partially supported by National Institutes of Health and National Science Foundation grants to Dr

M D Kamen. We thank Drs M D Kamen, T E Meyer and R W Holton for their interest and advice, and Dr M V Laycock for permission to include his unpublished *A. esculenta* sequence in Fig 2. *S. maxima* cells were a gift from Ing Hubert Durand-Chastel, Sosa Texcoco S A, Sullivan 51, Mexico 4, D F.

Corrigendum

The Editor has been advised that the authorship of the paper "Synthesis mimics of insect juvenile hormone" (*Nature*, 232, 486, 1971) does not accurately reflect the work done on the paper. With the concurrence of all the present authors, the name of Hwalm Lee (then of Stauffer Chemical Company) should be added as first author.

Errata

In the Matters Arising contribution "Changes in the latitude of the climatic zones of the Northern Hemisphere" by M K Miles and C K Folland (*Nature*, 252, 616, 1974) the following corrections are necessary. The second author's name should read Folland not Follard, in the legend to Fig 2 1970–37 should read 1970–73 and in the legends to Figs 1 and 2 subpolar flow should read subpolar low.

In the article "Particle acceleration in planetary magnetospheres" by M J Houghton (*Nature*, 251, 205, 1974) equation (1) should read $\sigma_{\parallel} \approx \omega_{pe}/(4\pi \times 10^8)$ mho m⁻¹ and not as printed.

In the article "Acetylcholine as an excitatory neuromuscular transmitter in the stomatogastric system of the lobster" by E Marder (*Nature*, 251, 730, 1974) choline acetyltransferase was printed incorrectly as acetylcholine transferase on three occasions. These were in the heading to Table 1, in the first line of the penultimate paragraph on page 730 and in the second line of the last paragraph of the article.

reviews

Independence and Deterrence: Britain and Atomic Energy, 1945-1952. By Margaret Gowing. Vol. 1: *Policy Making*; pp. xi+503. Vol. 2: *Policy Execution*; pp. xiv+559. (Macmillan: London and Basingstoke, November 1974.) £10.00 each.

THESE two volumes of official history are notable for Professor Gowing's mastery of her subject, the orderliness of her presentation of a complex story and the clarity of her style. She has much to say which scientists will find absorbing, and for the non-scientist she manages to explain as much of the technology as he is likely to be able to assimilate. Even more valuably she reveals the intimate processes of government with a wealth of the sort of detail which the public is rarely allowed to know until at least 30 years have elapsed. The earlier release in this instance indicates how quickly this initial phase of atomic policy has passed into history. "Very little", we are told, "has been modified or omitted on public interest grounds".

Some early comments about the book, because they focused on Professor Gowing's more critical passages, gave the impression that her work was a revelation of governmental confusion and muddle, with parliament and the nation being kept in the dark while objectives were being pursued which had never been adequately discussed, even within the government or in Whitehall. The criticisms are there all right but the overall impression derived from reading the two volumes is different. The major decision which the new government took after 1945—to develop a national atomic programme, with a national atomic bomb as its top priority—did indeed emerge in a somewhat messy way. Most of the scientists and officials engaged in the preliminary arrangements seem to have acted on the assumption that they were intended

to produce atomic weapons, well before the ministerial decision was finally taken early in 1947. Parliament, meantime, had shown little curiosity and when it was formally told in May 1948 that atomic weapons were being developed there was scarcely a ripple on the political waters.

Once that decision had been taken, the necessary priority was given to the project and was subsequently upheld by Prime Minister Attlee whenever it needed to be re-asserted.

The result was the trial explosion of the bomb at Monte Bello in 1952, which was a major technical achievement. The only possible criticism of the execution of the policy—that it might have been completed sooner—is shown by Professor Gowing to be of little importance. Given the overall limitation of British resources in manpower, money and materials, any speeding up could have amounted to no more than

a few months. Indeed, in both timing and cost the operation came much closer to the original estimate made for it than most other projects involving frontier technology have been able to claim. It was undeniably a success story.

The only inside critics of any weight who questioned the decision to make the bomb, were Patrick Blackett and Sir Henry Tizard. Blackett's memorandum of 1947, reproduced in full in these books, was a clear statement of a particular point of view, and no doubt it deserved fuller discussion than it received. But its rejection is not surprising. For Blackett made assumptions about the likely attitudes of the United States and the Soviet Union and also about the likely effect upon other countries of Britain deciding not to make atomic weapons, which were shared by scarcely any politicians or civil servants at the time and by only

a few of his fellow scientists. Even in retrospect his forecasts of what might result if various alternative policies were followed seem little closer to what actually occurred than do the predictions of anyone else.

In 1949 Sir Henry Tizard, having perceived sooner than most that Britain's relegation from the ranks of the great powers was likely to be irreversible, argued that she could not afford this symbol of great power status, which she would in any case be unable to make effective. But it seems that he would have wished to divert the funds into other defence programmes rather than into civilian atomic projects, about which he was unduly pessimistic.

Despite Professor Gowing's admirably balanced narrative, it is not always easy for the reader to keep in mind the developing international scene which provided the background for atomic policy. At the beginning, the future attitudes of all the wartime allies were in doubt; not the least of

The way it happened

Kenneth Younger

Ministry of Defence

these doubts concerned the likely attitudes of the US and USSR to one another. By the end of 1947 the Council of Foreign Ministers had finally broken down and anxiety about Soviet Policy in Europe was growing, reaching a climax with the Berlin blockade in the following year. British politicians, who had only just emerged from the second world war, found the outbreak of a third entirely credible. Moreover, they remembered just how it had felt in the pre-war years to be militarily outclassed by a potential enemy; and the only way to avoid a repetition of that was to cling to the American alliance. They were, however, still unsure, even in 1949, of permanent American military commitment in Europe and therefore found it impossible to contemplate throwing away the one major weapon in the development of which, they had reason to believe (though wrongly as it turned out), they were ahead of the USSR.

As regards the implementation of the programme, the heroes of the story are unquestionably the three men who led the main institutions entrusted with research, production of fissile material and weapons: John Cockcroft, Christopher Hinton and William Penney. All were supremely competent in their respective specialities and all showed an exceptional capacity for leadership of their teams. What stands out from Professor Gowing's story is that the quality of these men and their capacity to cooperate with one another triumphed over the complicated bureaucratic framework within which they had to operate. Even the absence, at certain periods, of clear central direction and coordination may have had its compensations in the flexibility which it allowed the scientists in changing their methods according to the state of the art. The supervising department—the Ministry of Supply—also deserves credit for having been capable of adjusting many civil service practices to the needs of a wholly unprecedented pioneering operation. In contrast, industry, with a few honourable exceptions, proved unimaginative and inadequate.

At the point when these volumes break off in 1952 a new phase, on which we are promised further volumes, was opening. Slowly the implications of the new weaponry—moral, political and military—came under public discussion. Almost equally slowly a realisation of Britain's changed world status came home to public opinion and with it an altered appreciation of the comparative importance of Britain's relations with the United States (which dominates the volumes already published), the Commonwealth and Europe.

How far the policies followed from

1945–52 may have prejudiced the subsequent evolution of British atomic policy, for better or for worse, will no doubt emerge as the story unfolds. 'Very little' would be my present verdict. What was done, I believe, in the immediate post-war years had to be done in the confused circumstances of that time, and in that sense was correct. The next phase was entirely different. Events such as the end of the Stalin era, the coming of the hydrogen weapon and the space programmes, and the rapid reduction of Britain's responsibilities as a world power from the late 1950s onwards combined to require a reassessment of Britain's role in nuclear weaponry.

Whether the choices which Britain then made were wise or not, we shall

hope to learn from later volumes, but I do not think that they were prejudged by what had gone before, except in the sense that if Britain had had no atomic programme she would have had little or no choice to make. For myself, having spent the years 1945–52 as a Labour MP, with a spell in the Foreign Office as a Minister (1950–51), I am a little surprised to find nothing in these volumes which, had I known of it at the time, would have radically altered my view of the role Britain should play. Nor would I have dissented from the atomic programme which was under way.

If this sounds a little like saying that because it happened this way, this was the way it had to happen, I can't help that. □

Varying aspects of fisheries work

Sea Fisheries Research. Edited by F. R. Harden Jones. Pp. xvii+510. (Elek Scientific Books: London, March 1974.) £10.00.

THIS book is a collection of 21 essays in honour of Michael Graham, former Director of Fishery Research with the Ministry of Agriculture, Fisheries and Food at Lowestoft. Graham commenced his career in fisheries research in 1920, and his early work on the North Sea cod and its fishery was, and still is, a model of investigation into fish biology, life cycles, spawning grounds, and age compositions. The study led to proposals for the better management of the fishery and was an outstanding contribution to the so-called theory of fishing, whereby attempts are made to establish parameters for growth, recruitment, and natural and fishery mortality. After the 1939–45 war Graham returned to Lowestoft as Director of Fishery Research, and immediately began planning for the postwar research effort by building vessels and recruiting staff of a calibre which has made the Fisheries Laboratory at Lowestoft, and its satellites at Conwy and Burnham-on-Crouch, respected throughout the world. Graham retired in 1958 and characteristically applied himself to the environmental reclamation of colliery waste tips, and to lecturing. Sadly, he did not live to see the publication of this book, but one feels that he would have approved of this collection of essays by his former colleagues.

Naturally, the varying aspects of fisheries work are well covered. Papers on the exploitation of stocks of fish and shellfish are much in evidence. M. J. Holden's thoughtful paper on the rational exploitation of elasmobranch populations suggests how vulnerable to extinction most of them would become

if heavily exploited. That is supported by A. C. Burd's requiem for the North East Atlantic herring and its virtually extinct fishery, a classical example of the failure of some fishery scientists to accept the evidence of others, and the consequent lack of international co-operation. The world resources of hakes of the genus *Merluccius* are discussed by B. W. Jones, who suggests that several species are still underexploited, although some, notably the European hake (*M. merluccius*), have been heavily overfished. In an essay on the world's industrial fisheries (that is, fisheries which produce fish meal and oil), C. T. Macer confirms that some hakes, especially the western South American species-group (*M. gayi*), might support a greater fishery than at present. A contribution from P. R. Walne discusses the problems of the shellfish industries of England and Wales. He also considers the fascinating possibilities allowed by the development of successful culture techniques, for which most of the biological requirements have already been established.

It is suspected that the pollution of inshore waters is one of the factors responsible for the low rate of recruitment of young individuals to many native shellfish populations. In the Essex oyster fishery the total catch declined as the human population, and the consequent pollution of the area, increased. H. A. Cole takes a broader look at pollution in his essay on marine pollution and the UK fisheries, and he concludes that there is little evidence that the discharge of industrial and domestic waste into the sea has had a deleterious effect on sea fisheries. In support of this he cites the increase in landings of plaice, cod, and haddock in the North Sea, and plaice and cod in the Irish Sea (both are enclosed and relatively polluted seas). Changes of

this nature may be, however, a direct result of fluctuations in year-class strength, and of changing climatic conditions, both factors may mask the adverse effects of pollution

Several of the essays are concerned with technical subjects R W Blacker's discussion of recent advances in otolith studies is an important contribution to the methods of study and interpretation of otoliths for age determination (a 'traditional' fisheries' tool) By contrast, Alan Jamieson and C E Purdom present new techniques in fisheries research with essays on the study of genetic tags for marine fish stocks, and genetic variation in fish The volume also contains a contribution on the design of research vessels by Geoffrey C Trout, as important a study as any attempted at Lowestoft (and as one who has sailed on FRV *Cirolana*—the newest of the fleet of research vessels—I can vouch for the excellence of the product

The quality of production of this book is excellent, although the photographic illustrations do not reproduce well The editing is even and unobtrusive and must have represented a formidable task for the editor Altogether this is an admirable and fitting volume in honour of Michael Graham

Alwyne Wheeler

Liquid crystals

The Physics of Liquid Crystals By P G de Gennes (The International Series of Monographs on Physics) Pp xi+333 (Clarendon Oxford, Oxford University Press London, June 1974) £11.50

THIS is the first modern book to survey and discuss the physical properties of liquid crystals Liquid crystals combine some of the properties of the crystalline and of the isotropic liquid phases, they have received considerable attention during the last 10 years The re-discovery of electro-optical effects, which are used in liquid crystal display devices, has led to a revival of basic research on the physical and chemical properties of liquid crystals, both theoretically and experimentally Their study is complicated because it involves various physical and chemical disciplines, making it almost impossible to cover all the aspects in one book Although the main physical topics are discussed or at least mentioned in this book, the main emphasis is on hydrostatic and hydrodynamic properties which, in principle, also determine the optical properties

In Chapter 1 there is a short introduction to the nature of the different liquid crystalline phases and of the constituent molecules The following four

chapters, the major part of the book, deal with the nematic liquid crystalline phase which is characterised by long range, orientational ordering of the constituent, rod-like molecules

Chapter 2 deals with long and short range order Different order parameters are introduced and linked to measurable quantities, such as nuclear magnetic resonance spectra, the anisotropy of magnetic susceptibility, and so on Some theories of orientational ordering are reviewed briefly Finally, short range order effects near the transition from the isotropic to the nematic phase are discussed The static, elastic distortions in a nematic single liquid crystal are treated in Chapter 3 There, a hydrostatic theory based on a continuum description is introduced and discussed thoroughly, and the role of boundary effects and boundary conditions is made clear Various applications of the theory, and some instructive problems are given Most are concerned with deformations induced by external magnetic and electric fields for different boundary conditions Close attention is also given to the strong natural light scattering, which is analysed in terms of spontaneous orientation fluctuations

Chapter 4 describes distortions that are not continuous but which involve singular points or lines These defects, where the orientation varies discontinuously, are called disclinations In connection with disclinations different textures are discussed

An understanding of the coupling between orientation and flow is essential to any consideration of hydrodynamic properties That problem, and the different approaches to it, are discussed thoroughly in Chapter 5 Again various applications and experimental situations are described, including classical flow experiments, flow induced by external fields, inelastic light scattering, dynamic scattering, and so on

The cholesteric liquid crystalline phase, essentially a helically distorted nematic phase, is also discussed Because of the helical structure this phase has rather peculiar optical properties which are discussed in a rather formal way The hydrostatic and hydrodynamic theories of the nematic phase are extended to a discussion of the cholesteric phase The static distortion of the helical structure by external fields, flow properties, the analogue of dynamical scattering and other typical phenomena are considered and some typical defects and textures are also described

The last chapter is devoted to smectic liquid crystals In addition to the orientational ordering they have a layer structure First, a classification and description of the different smectic phases is given, and then attention is restricted

to the A and C-phases In the discussion of the static and dynamic properties the role of the layer structure is clearly displayed Again, attention is given to distortions induced by external fields and mechanical forces, to light scattering, the propagation of acoustic waves and flow properties The chapter ends with a description of phase transitions and precritical phenomena

Though various experimental methods and experiments are mentioned or briefly described, the main emphasis is on the theoretical aspects The approach to these aspects, which is purely phenomenological, is based on the fundamental hydrostatic and hydrodynamic equations The study of chapters 3 and 5, which form the central part of the book, is therefore necessary before the chapters on the cholesteric and smectic phases can be understood One may regret that little or no attention has been given to molecular theories and considerations, as these have been quite successful and instructive Some of the discussions are rather formal and general, whereas others are more concise, but the material is nevertheless presented in a clear and systematic way

This is a most valuable book which gives a comprehensive though not easy introduction to many aspects of the liquid crystalline phases

W. J. A. Goossens

NEW FROM DENT

Everyman's Astronomy

EVERYMAN'S
REFERENCE LIBRARY

Edited by R H STÖY
Deputy Director of the
Royal Observatory, Edinburgh

The successor to *Astronomy for Everyman*, this is a completely new book providing the intelligent layman with a compact and reliable guide to astronomy The eleven chapters are written by specialist professional astronomers and, while complete in themselves, cover the broad field of modern astronomy A special point has been made of including significant recent developments

Energy and fat

Energy Balance and Obesity in Man
By J S Garrow Pp xii+335 (North
Holland Amsterdam, London, American Elsevier New York, 1974) Dfl.80,
\$30.80

THIS is a very well written, highly persuasive, important book which provides all the basic and practical information necessary for an understanding of the problem of obesity.

The trouble with 'obesity' is that it produces emotional reactions which people rationalise from a literature that provides any evidence desired. In medical science there can be few pursuits which affect such large numbers of people with such little effect, as the investigation and treatment of obesity. Of course, few things are as satisfying to the intellectual academic as a problem with little prospect of application to a real-life situation, and that may explain the large volume of contradictory literature on this subject.

In a slightly lengthy introduction, Dr Garrow initiates us into his positive interpretation of this mass of confusing information. His book reviews comprehensively the different methods used to measure the intake and expenditure of energy in man, the theories of the control of energy intake, the part played by physical activity, energy expenditure, and the variable composition of the human body in relation to fat and how this can be measured. The final section is concerned with the difficult, practical problems of how to diagnose and classify an obese patient and includes a critique of the likely effectiveness of the various forms of treatment.

My only serious criticism of this excellent book is that, possibly because the author has apparently become actively interested in obesity only comparatively recently, his interpretation frequently seems biased and somewhat selective. He fails to quote certain relevant literature, especially from the large volume of physiological papers on exercise, and he is perhaps slightly too dogmatic in many of his statements. In those sections in which he has first-hand knowledge—for example, the chapter on "Energy stores: their composition, measurement and control"—he writes clearly and dispassionately in a most stimulating fashion.

I have no hesitation in recommending this book. To my knowledge, it is by far the best book on the subject of energy balance in man. It should be read by everyone involved in the study of obesity—though all should retain certain reserves about accepting totally some of Dr Garrow's views.

J. V. G. A. Durnin

Is the 'crunch' really coming... Chemistry and the needs of society

This unique and timely volume brings together a wealth of hard fact and informed opinion concerning many of the pressing problems facing society today—and tomorrow.

The energy crisis, the threatened water shortage, the problems of feeding the growing numbers of our species, environmental pollution, 'the quality of life' in several of its aspects, future economics of industrial innovation and new materials in place of old, education, training, and research in the Universities, all these topics are discussed by authorities in the respective fields. The underlying theme is the role of the chemist in creating, maintaining, and improving the conditions responsible for the high standard of living which we in the Western World take for granted.

obituary

S. Petterssen

SVERRE PETTERSSSEN, the outstanding meteorologist, died in London on December 31. He was 76.

Born in Norway, Petterssen served in the Norwegian Meteorological Service from 1924 to 1939 after graduating from Oslo University. In 1939 he became Professor of Meteorology at the Massachusetts Institute of Technology, and came to England in 1942. During the war he was stationed at the Meteorological Office at Dunstable, establishing now standard techniques of upper air analysis. In recognition for his services, he was made CBE in 1948 and Commander of the Order of St Olaf in 1949.

After the war Petterssen returned to Norway, serving in the Norwegian Weather Forecasting Service until 1948, when he was appointed Director of Scientific Services of the US Air Force Weather Service. In 1952, he returned

to academic life as Professor of Meteorology at the University of Chicago. In the next ten years, he played a large part in the rapid expansion of research and education within government and academic institutions.

Petterssen's contributions to the theory of frontogenesis and convection, to the kinematics of weather systems and to the physics of fog were highly original, and led the way towards more quantitative methods of weather forecasting.

H. Heller

HANS HELLER, the distinguished endocrinologist, died on December 30 at the age of 70.

Born in Brno, Professor Heller studied Natural Sciences at Cambridge from 1929 to 1931, when he was

appointed to a post in pharmacology at the University of Vienna. He returned to England in 1935 to obtain medical qualifications at University College Hospital. He worked there as a Beit Fellow until 1941, when he took an appointment at Bristol University, becoming Professor of Pharmacology in 1949.

Heller was particularly famous for his investigations of the water balance effect of neurohypophyseal hormones in amphibia, showing that the water-balance principle differed from that of mammals, later isolating the hormones from cod in 1959. His research into the nature of such hormones in other animals illustrated a pattern for the evolutionary development of the hormones.

From 1963 to 1974, he was editor of the *Journal of Endocrinology* and at the time of his death was chairman of the Society for Endocrinology.

announcements

Awards

New Year's Honours

Max Ferdinand Perutz has been made a Companion of Honour for services to molecular biology.

Knights Bachelor include **Arthur Llewellyn Armitage**, vice-chancellor, Victoria University of Manchester, **Frederick Arthur Bishop**, Director-General, National Trust, **Harold Montague Finnieston**, FRS, chairman, British Steel Corporation, **Hugh Ford**, FRS, Professor of Mechanical Engineering, Imperial College of Science and Technology, **Ieuan Maddock**, FRS, chief scientist, Department of Industry, **Edward Eric Pochin**, lately director, MRC Department of Clinical Research.

Erik Erikson, Professor of Psychiatry at Harvard University, has been awarded the **Mental Health Association Research Achievement Award** at the organisation's annual meeting in Washington.

Godfrey Hounsfield has been awarded the **Wilhelm Exner Medal**, a major Austrian award, for the invention of the EMI computerised X-ray brain scanner.

Appointments

Henry Francis Black has been appointed to a personal chair of mechanical engineering at Heriot-Watt University.

Miscellaneous

Mitchell Prize The Mitchell Energy & Development Corporation, in association with the Club of Rome, is to make biennial awards for papers submitted on the problems inherent in the transition from growth to equilibrium of population, material consumption and energy use over the next 40 years. Application deadline for 1975 is February 28. For information contact **Limits to Growth '75**, 5645 South Woodlawn Avenue, Chicago, Illinois 60637.

The Food and Drug Administration's OTC Panel is interested in receiving any unpublished data on foetal damage or loss associated with the maternal use of vaginal contraceptives or douches. For information, contact **Elizabeth B. Connell**, Food and Drug Administration Bureau of Drugs, Division of OTC Drug Evaluation (HFD-510), 5600

Fishers Lane, Rockville, Maryland 20852.

The **Moscows Seminar on Collective Phenomena** will be held every Sunday at noon, on a broad range of scientific topics. For information, contact **I and V. Brailovsky**, pr Vernadskogo 99, korp(bldg) No 1, kv (Apt) 128, Moscow.

Lady Tata Memorial Trust Applications are invited for scholarships and fellowships to aid research on leukaemia and allied conditions. Further information may be obtained from Secretary (European) Scientific Advisory Committee, Lady Tata Memorial Trust, Chester Beatty Research Institute, Fulham Road, London SW3.

A. E. Bennett Research Awards The Society of Biological Psychiatry is offering two awards—one in basic and one in clinical science—for the purpose of stimulating worldwide research in biological psychiatry by young (under 35 years) investigators. Further information from Chairman, Committee on Research Awards, Veterans' Administration Hospital, Brockton, Massachusetts 02401.

Amber light for genetic manipulation

THE report of Lord Ashby's working party (Cmnd 5880, HMSO, 26p) makes it seem more likely than not that biological research involving the "manipulation of the genetic composition of micro-organisms" will continue in Britain, but in an atmosphere which takes account, chiefly through the laying down of proper laboratory procedures, of the possible attendant hazards. Stated like that, it all sounds eminently reasonable, but just what will happen next, and how hazard-proof can the eventual safety arrangements hope to be?

The working party finds that the possible benefits which may accrue from the continuation of such research are great—for example the 'mass production' of genes responsible for promoting the synthesis of insulin and the like. The report also describes the possible hazards (and says that there is always the possibility of these emerging in a completely unexpected way). Weighing the two sides up, the conclusion arrived at is that provided the precautions mentioned in the report are "taken by trained and disciplined workers, the potential hazards could be minimised, and the potential benefits would amply repay the trouble and expense which the precautions would involve". That is the report's thesis in a nutshell.

The real question is whether it is possible to impose from scratch, on scientists and technicians who have not been used to them, the disciplines of institutions that deal on a day-to-day basis with pathogenic organisms—those responsible for cholera and rabies, for example. It is certainly more difficult to persuade a whole laboratory that it must adopt new and time-consuming procedures than to convince an individual scientist, joining, say, a public health laboratory, of the necessity for all the precautions he finds there. The matter is made more difficult because the cholera vibrio is dangerous, period, whereas many of the genetic alterations brought about by cutting and joining pieces of bacterial DNA, or tampering with viruses, may or may not be harmful to humans. Alas, it would be all too human to pay only lip service to the best of precautionary arrangements, for that very reason. It is a salutary thought that even laboratories dealing with the smallpox virus are not immune from accidents of the type which caused the smallpox outbreak in London in 1973.

Containment procedures are, of course, important in the context of microbial genetics, but should they be the first line of defence as the working party suggests? The working party discusses several back-up procedures, including epidemiological studies on people carrying out work on genetic engineering of micro-organisms, and mentions ways in which, without prejudice to the science, at least some micro-organisms of interest could be made safe from the start. One possibility is to "dis-

arm" potentially dangerous plasmids or bacteria by altering their genetic composition a bit more so that, for example, useful but possibly unsafe strains of *Escherichia coli* could not survive in the human gut because the chemical environment or the temperature were wrong. (Those dealing with the most dangerous 'conventional' pathogens do not, of course, have that option open to them.) This is potentially a much more watertight approach than: a micro-organism may be able to survive in the human gut, it could be dangerous, so it should never get there.

Other ways of thinking have been canvassed—for example that the most dangerous experiments should be done in a few secure establishments—but where is the border line, what is a 'dangerous' experiment? In any case there would probably be scant support for the idea that a major growth area in the biological sciences should be confined to a few selected laboratories.

Much of the working party's report is, rightly, devoted to the risks to humans that might attend genetic manipulation of bacteria. But there is, as the report acknowledges, an "analogous risk" from similar work on animal and plant diseases. Here containment is very much the order of the day, is accepted as such by those involved, and in the case of some dangerous organisms is already backed up by legislation.

Assuming that the main thrust of Lord Ashby's report is accepted, what will happen next? The document is for discussion, and discussed it will be, especially at the conference at the end of this month arranged by Professor Paul Berg, one of the instigators of the National Academy of Sciences moratorium. The institution of a code of practice was recommended by the Ashby working party, but it was not within its brief to come up with chapter and verse. In Britain, there is already a body that might fit the bill—the Godber Committee, which is examining safety procedures in the laboratory use of dangerous pathogens following the 1973 smallpox outbreak. This working party is expected to report soon. (One of the suggestions made in the Ashby report is that a biological safety officer should be appointed wherever the experiments in question are to be carried out. That would not be sufficient, and in practice a system of inspection would be the only real way of keeping things up to scratch.)

Whatever happens, the Medical Research Council has stated that it will allow the research to go on, but accompanied by containment precautions of its own if nothing is imposed from above. The universities (through the University Grants Committee) have also taken the points made in the report and are examining in detail the situation as it affects them with a view to setting up their own rules. □

Immigrants at Lod airport. Photo Enka.

Coping with an exodus

The Soviet government's refusal to accept the conditions of the trade agreement with the United States has left in an equivocal position the Russian Jews waiting to leave their country. Meanwhile, Israel carries on with a reception programme which has handled 100,000 immigrants since 1970. Vera Rich reports from Tel Aviv.

THIS month, the 100,000th Jewish emigrant to leave the Soviet Union since 1970 arrived in Israel. In spite of Soviet claims that 98.5% of all Soviet Jews wishing to emigrate are allowed to do so, there is known to be a backlog of some 140,000 applicants still awaiting permission to leave. Although the effect on Jewish emigration of the recent Soviet rejection of the US-Soviet trade agreement cannot yet be gauged, there is no indication that it will lead to any official change of policy—indeed, a statement made by Colonel Alpachnikov of OVIR (the visa department of the Ministry of the Interior) on January 17, the day after the rejection of the agreement was announced, suggests that the policy will remain as before, one of frustrating delays and harassment, but with no absolute bar to emigration. The flow of Soviet Jews arriving in Israel may well slacken off for at least a time, but so far there are no signs of a total halt.

The problems of absorbing these immigrants into the Israeli economy are well known, and have become, indeed, the subject of a number of wry Israeli jokes ("What does one do with 50 professors of Russian philology?"). The

situation is aggravated by the fact that, on the one hand, some of the newcomers have a higher education and wish to continue to work in a learned profession, and, on the other hand, this higher education is sometimes so extremely specialised that even the smallest change of employment amounts virtually to a change of metier (one young engineer, at present going through the absorption process, quoted his first degree as having been in "Strength of Materials of the Aircraft Construction Industry"). And even those scientists who are able to be absorbed directly into Israel's higher education and research system may well find their practical problems only just beginning.

The problem, for a recently arrived scientist from the Soviet Union is largely one of adjusting his or her mental attitude from that of state-run, state-controlled research, to what has been described as the "anomic situation" of Israeli academic life. For the first time, they are faced with the problem of justifying their proposed research on an economic basis. It is not only the problem of what Israel can afford to pay for (some subjects such as

high energy particle physics which can only be tackled on a multinational or superpower budget, are clearly ruled out); they have to cope with a whole new system of funding projects and buying materials. Coming from a system where new graduates are directed into industry or research, they have no experience of such basic procedures as interviews and applications. Some are distressed by lack of 'status'—the new immigrant working in an Israeli academic institution has his salary paid for the first two years by the government, a situation which bypasses the current cut-backs and redundancies necessitated by Israel's economic situation, and also somewhat relieves the budget of the department concerned, releasing funds for equipping the immigrant scientist for his research. During these two years, however, he is essentially on probation and his appointment still awaits confirmation. Coming from the Soviet system, where the status of a scientist is extremely high, some scientists seem to find difficulty in accepting, even temporarily, a position in which they have a salary but no status.

It is easy, of course, to exaggerate the importance of such difficulties—and the comments of the scientists themselves must be treated with a certain discretion. Many have, after all, chosen to come to Israel since they feel that the Soviet system is not conducive to academic freedom. One physicist in particular, who, when interviewed about his reactions to working in Israel, took advantage of the opportunity to offer extensive criticism of the absorption process, and, indeed, of the Israeli economy and political system, concluded by saying that he loved living in Israel "for here I can criticise as much as I like." Many criticisms seem to arise from a sense of enthusiasm. Scientists settled in a job have anecdotes of friends awaiting absorption, who want "to use their resources and experience" for their new country. More organisation is needed, they urge. "Here, in Israel, all things go slowly."

To hasten the process, the Israeli government set up, at the end of 1973, a Centre for Absorption in Science, under the auspices of the Ministries of Labour, Absorption, and Finance, and of the *Sochnut* (Jewish Agency). It is staffed by seven 'professionals'—themselves scientists who felt that their real metier lay in administration rather than research—assisted by a small secretarial staff. Doctor Uri Horowitz, Director of the Centre, explains their task of that of "intervention to get the scientist into the centre of his own communications network", in other words, to familiarise him with the whole job-finding routine and to introduce him to the various contacts he will need in his professional

life. Although the centre does not deal exclusively with immigrants from the Soviet Union, they do, in the present circumstances, form the majority of its clients. The centre aims to promote the good of the scientist rather than the product, and, accordingly, the new immigrant is presented with a set of forms to fill in, in his own language, with questions structured according to what he expects in an enquiry of this kind—even if, in certain cases, the information is irrelevant to the needs of the centre. Having completed his forms, the immigrant is interviewed and questioned about the work he would like to do. He is then asked to write a feasibility study of his proposed project, with the emphasis on the part he himself would play in it. (It seems that some idealists have submitted projects which they feel would benefit Israeli science, but have forgotten to write in a job for themselves.) After completion of this study, the centre then discusses ways and means of fitting the scientist and his proposed project into the existing structure of Israeli science.

In general, the impression gained from interviews with scientists who have been absorbed is that remarkable efforts have been made to keep them within their same general discipline. Some of the cases of "change direction" quoted prove on investigation to be nothing more than change of employment. Thus the Kinneret research station (attached to the Technion) has absorbed five immigrants from the Soviet Union, only one of whom is a limnologist, the other four being physicists and chemists, who are, however, still working in their original fields, although now on the physics and chemistry of lake water. The need for 'retraining' often referred to may cover nothing more than the need of a computer expert to learn a new programming language. Some scientists arrived with a choice of interests, and have found their subsidiary interests in Russia can be their main interest in Israel. The main problems seem to arise with those who qualified not in one of the big state universities, but in a small Institute of Higher Education, where the subjects taught are extremely narrow and the graduate is, by western standards, more an applied technologist than a scientist. For some of these, retraining becomes, in effect, a chance to bring one's education up to full academic standard, and to advance from being, say, a computer technician, to a systems programmer.

Even for the best qualified scientists, there is, on arrival in Israel, generally a backlog of study to be made up. Under the current Soviet practice towards academic would-be emigrants, application for a visa is followed by a number of forms of harassment, including

dismissal from professional employment and the cutting off of one's telephone, which entails long and tedious journeys to arrange even the simplest details connected with one's hoped-for departure. If, as is often the case with scientists, the initial application is rejected, one may spend months or years as a "refusnik", with neither the opportunity nor the necessary time to keep up one's reading or think about one's own research. (The famous 'Sunday seminars' were started as an incentive to scientists in this position to attempt to keep up their work. On arrival in Israel, therefore, the scientist is not only faced with learning a new language, but with making up vast arrears of essential reading.

As far as possible, the universities do assist in the problem of learning Hebrew. The Ben-Gurion University (Beer Sheva) employs its immigrants on a kind of sandwich-course basis, half their time being devoted to studying Hebrew. Tel Aviv University, which has absorbed some 280 immigrants (including postgraduate students) has its own *ulpan* (Hebrew school for immigrants). The backlog of reading presents a greater problem—and is one cause, in the case of long term "refusniks", of scientists deciding not to continue in their chosen profession but to turn to some other field of activity like administration. Once an effort is made, however, and the reading started, the greater and more rapid availability of journals, and the chance to correspond freely with colleagues throughout the world, begin to show results and the information gap is rapidly reduced.

This freedom of correspondence, and the chance to work on one's own initiative, instead of as part of a closely controlled team subject to state direction, are seen by the scientists as the greatest benefits of their new academic life. The universities in their

turn find the immigrants from the Soviet Union a source of new vitality and expansion. The Pure Mathematics Department at Tel Aviv University was "virtually non-existent" until the wave of Soviet immigrants arrived; now it is acquiring a considerable reputation and the university is hoping to expand its Astronomy Department in a similar manner. The Ben-Gurion University, having absorbed seven Soviet pure mathematicians into senior teaching posts, is making tentative plans (subject to funding) to develop an Institute of Applied Mathematics that could take, initially, about 20 or 30 applied mathematicians. This university also offers considerable scope to Soviet scientists, especially those dealing with the more applied branches of physics and chemistry, in its raw materials programmes, and also to agronomists in its desert research programme. The vast scientific complexes of the Technion and the Weizmann Institute likewise still seem to offer considerable possibilities for absorbing further immigrants. The main problem remains that of funding—but Israel has a long history of foreign endowments for academic institutions and, in spite of economic difficulties, one feels that in the long run the money will be found.

Although an upper limit to absorption must at some time be reached—if only when the whole state of Israel is transformed into one vast academic campus, coterminous with the state frontiers, with the entire population either engaged in academic research or providing the ancillary services to keep the academics alive (the "think-tank of the western world", as one scientist described it)—that time has not yet come. And in the meantime, Israel provides a fascinating case study of the problems of transition from state-controlled research to one based essentially on personal initiative. □

Immigration officials check the papers of Viktor Polski, on arrival in Israel.

international news

SSTs: it's an ill wind . . .

by Colin Norman, Washington

THE United States Department of Transportation last week made public the results of a three-year investigation (costing \$20 million) of the likely environmental effects of supersonic aircraft flying in the stratosphere. The event was a mixed blessing for the financially beleaguered Anglo-French Concorde project.

First, the study reached the conclusion that the present number of supersonic passenger aircraft (SSTs), together with those now scheduled to enter service, would cause climatic changes which will be too small even to measure. But that conclusion comes as no surprise since sales of Concorde have been so dismal that a maximum of only 30 SSTs are expected to be flying by the late 1970s (about 16 Concorde and 14 Soviet TU-144s)—a number which is unlikely to represent a threat to anything except Britain's balance of payments.

More ominous news from Concorde's point of view is that the study has essentially confirmed the validity of the much publicised theory that a large fleet of SSTs, equipped with present-day engines, could damage a layer of ozone in the upper atmosphere which shields the Earth from ultraviolet radiation. Consequently, if the size of the SST fleet increases significantly, serious environmental damage could result unless the aircraft are fitted with cleaner engines, the study indicates. The argument about the effect of SSTs on the environment is, therefore, unlikely to be stilled by this report.

Called the Climatic Impact Assessment Project (CIAP), the study was ordered by Congress after fears about the effect of SSTs on the ozone layer had played a key role in the Senate's momentous decision in 1971 to terminate development of an American SST. The basis for those fears has been hotly debated ever since.

The theory, put forward in 1970 chiefly by Dr Harold Johnston of the University of California, was that oxides of nitrogen, spewed into the stratosphere by jet engine exhausts, would upset the delicate chemical equilibrium of the ozone layer, destroy a part of it, and cause an increase in the amount

Concorde, accelerating at 35,000 feet

of short-wavelength ultraviolet radiation reaching the Earth's surface. One consequence would be to increase the incidence of skin cancer—an emotive topic if ever there was one.

Although it has turned out that Johnston's calculations (*Science*, 173, 517; 1971) overestimated the effect of SSTs on the ozone layer, chiefly because they were based on erroneous government projections of the size and character of the SST fleet in the mid-1980s, the CIAP study has not refuted Johnston's theory.

The CIAP's report states that although there is still some uncertainty in parts of the calculations, a cause-effect relationship between operation of SSTs in the stratosphere and increased ultraviolet radiation reaching the Earth's surface has been firmly established. The extent to which a given increase in ultraviolet radiation will increase the incidence of skin cancer is more uncertain, the study suggests, but again, a link has been established.

Proceeding from the undisputed assumption that pollutants injected into the stratosphere can stay there for periods of three years or more, the CIAP report argues that the problem is not confined solely to supersonic aircraft since some wide-bodied subsonic jet airliners now fly in the lower stratosphere.

But how great is the effect? According to calculations presented in the report, the fleet of subsonic jets now in operation, which includes about 7,000 aircraft operating in the lower stratosphere, is probably depleting the ozone layer by about 0.1% over the next ten years, and the 30 or so SSTs which will be flying in the next few years can be expected to add a further 0.1% depletion. Those effects are, however, much too small to be detected since the minimum change in ozone level that could be picked up by a global monitoring

system, operating daily for 10 years, is about 0.5%, the report notes.

According to Dr Alan J. Grobecker, Director of the CIAP, it would take about 125 Concorde-class SSTs flying in the stratosphere for between four and five hours a day to reduce the ozone layer at the minimum detectable rate. Grobecker pointed out in an interview last week, however, that if demand for SSTs picks up in the early 1980s, it is conceivable that 70 Concorde and a similar number of TU-144s could be in service by 1990, which would cause at least a measurable change in the ozone layer.

To put those figures in perspective, however, the study points out that the ozone layer is about three times thicker at the poles than it is at the equator, so that there is considerable natural geographic variation in ultraviolet flux reaching the Earth's surface. Moreover, the distribution of ozone at a given locality can fluctuate by up to 25% from day to day. Set against those natural variations, the change likely to be caused by the SST is relatively minor. But the study notes that a small change in the average amount of ultraviolet radiation around the world may result in a relatively large absolute number of skin cancers. And that is not a prospect which government regulators can take lightly.

Thus, if the size of the SST fleet increases, the report recommends that SST engines should be redesigned to reduce the emission of oxides of nitrogen. Studies conducted by NASA have indicated that emissions of oxides of nitrogen from Concorde-type engines could be reduced by a factor of six without sacrificing performance, but it would cost about \$50 million and take up to 15 years. A more radical engine redesign, to reduce emissions by a

factor of 10 or more, would take up to 25 years, the report notes.

"If it can be made clear, very soon, that such reduced emissions will be required of aircraft of all nations, and if design to reduce those emissions is incorporated promptly into ongoing engine development, ozone reduction could then be kept near the current reduction due to aircraft alone (less than 0.1%) . . . for fleets up to 4,000 747-class subsonics at 11 km (38,000 feet) or 1,000 at 13 km (43,000 feet), and for 150 Concorde/TU-144-class SSTs", the report calculates. Over the longer term and with the more radical engine redesign, "stratospheric air travel could expand as a function of demand without affecting the environment adversely, in keeping with deliberate calculable standards enforcement".

The key to those sanguine predictions is early development of international standards to force SST emissions to be lowered. But, given the tortuous history of attempts to regulate emissions from automobiles in the United States, that will be no easy task. Nevertheless, the report argues that "the process of establishing and meeting standards should start now because of the long lead times involved".

As for the biological effects of increased ultraviolet radiation resulting from the operation of SSTs in the stratosphere, the CIAP report states that the percentage increase in ultraviolet flux is about twice the percentage decrease in the lower ozone layer. Thus, the smallest detectable depletion of the ozone layer—0.5%—would increase ultraviolet flux by about 1%. Though the effect of such an increase on the incidence of skin cancer is not readily calculated, the report notes that an upper level effect can be calculated by postulating that ultraviolet radiation plays the only role in development of non-melanomic skin cancer. An increase of 1% in ultraviolet flux would therefore cause an increase of 1% in the number of skin cancers.

In addition to those suggestions, the CIAP report also notes that another possibly serious problem with a large number of SSTs is that sulphur compounds in jet fuel could end up as solid particles of sulphuric acid floating in the stratosphere. The effect of that would be to filter out some of the solar energy reaching the Earth, which in turn could reduce the mean global temperature. Although it would take a very large fleet of SSTs to produce a detectable effect, the report notes that a difference of only a fraction of a degree would cost hundreds of millions of dollars in crop losses. The report therefore suggests that consideration be given to regulations to force high flying aircraft to use low-sulphur fuels. □

India's space programme

from Narender K. Sehgal, Jullundur

INDIA'S modest space programme is facing rough weather. Until about two to three years ago, things were going fairly well and were not too far behind schedule. Then generally difficult economic conditions, coupled with inflation and rising costs, began to take their toll. Funds have since been scarce and slow in coming, so important projects are running late, and some have had to be curtailed or postponed. Others face an uncertain future as decisions on them are kept pending.

Space research formally began in India with the creation of INCOSPAR (the Indian National Committee for Space Research) in the Department of Atomic Energy (DAE) in 1962. The programme started off with the launchings of sounding rockets from the Thumba Equatorial Rocket Launching Station near Trivandrum, mainly for meteorological and ionospheric investigations in the upper atmosphere. Following administrative and organisational changes over the years, ISRO (the Indian Space Research Organisation), a body under the Department of Space, took over responsibility for all matters relating to the country's space programme in 1969.

From small beginnings in 1963, when the Thumba station became operational, the programme has grown steadily and now covers a whole range of activities relating to rockets and satellites. The Space Science and Technology Centre (SSTC) near Thumba is the research and development unit of ISRO and is responsible for (1) work on systems and their components required in space research; (2) carrying out pilot production of equipment resulting from such work; and (3) developing an indigenous satellite launch capability not only linked to scientific exploration but also to communications, meteorology and remote sensing.

Besides the Thumba station and the SSTC, several other establishments are also engaged in work connected with different aspects of the research programme.

According to original plans, the high spot of India's space programme—the orbiting of an Indian satellite taken up and Indian rocket launched from Indian soil—should have been attained during 1974. By the end of 1972, however it had become quite clear that work on the project was running behind schedule and that the launch would not be possible before 1977. Apparently, the delay was mainly because of difficulties with the satellite
